

A Unified Theory of Cities*

Jacques-François Thisse

Matthew A. Turner

Philip Ushchev

Abstract: How do people arrange themselves when they are free to choose work and residence locations, when commuting is costly, and when increasing returns may affect production? We consider this problem in a framework with discrete locations and households with heterogeneous preferences over workplace-residence pairs. We provide a general characterization of equilibrium throughout the parameter space. The introduction of preference heterogeneity into an otherwise conventional urban model fundamentally changes equilibrium behavior. Multiple equilibria are pervasive. Stronger increasing returns to scale need not concentrate economic activity and lower commuting costs need not disperse it. The qualitative behavior of the model as returns to scale increase accords with changes in the patterns of urbanization observed in the Western world between the pre-industrial period and the present.

1 Introduction

Two centuries ago, one human out of ten lived in a city, incomes were a fraction of their present level, and commuting occurred on foot. Today, more than half of the world's population is urbanized, and commuting by foot is a curiosity in much of the world. The process of urbanization is widely understood as a contest between increasing returns to scale in production and the cost of commuting. Returns to scale in production leads to highly concentrated employment while commuting allows people to live at lower densities than those at which they work: as returns to scale increase and commuting costs fall, cities grow.

We investigate how the organization cities is related to the strength of returns to scale and to the cost of commuting. Our problem is to understand how people arrange themselves when they are free to choose work and residence locations, when commuting is costly, and when some form of increasing returns may affect production. We consider this problem in a framework with stylized discrete geography and households with heterogenous preferences over workplace-residence pairs. We provide a general characterization of equilibrium throughout the parameter space. In particular, we describe the implications of arbitrarily strong increasing returns to scale for the organization of cities.

The contest between increasing returns to scale and commuting costs does not play out as the conventional wisdom suggests. Qualitative features of an equilibrium city depend sensitively on the strength of returns to scale in production. When production is not constant returns to scale, corner equilibria where production concentrates in a subset of the available locations must always occur. With constant returns to scale or weak increasing returns, there is a unique interior equilibrium, economic activity is centralized, and stronger returns to scale concentrate economic activity. When increasing returns to scale are moderate, multiple stable interior equilibria may occur and stronger returns to scale disperse economic activity. When returns to scale are strong, the interior equilibrium is unique and stronger returns to scale continue to disperse economic activity. That is, the conventional intuition that returns to scale are an agglomeration force need not hold for sufficiently strong increasing returns to scale. Our findings about commuting costs are equally surprising. We find that economic activity disperses both when commuting costs are high and when they are low. It is only at intermediate levels of commuting costs that highly concentrated economic activity can arise. That is, when the location of production and residence is endogenous, the standard intuition that decreases in commuting costs must disperse economic activity need not apply.

Our investigation is important for a number of reasons. First, we address a foundational problem of urban economics. While much progress has been made, existing work relies on strong simplifying assumptions and arbitrary restrictions on the strength of agglomeration forces. For example, the workhorse monocentric city model sets the location of work exogenously, while recent developments based on quantitative spatial models require assumptions prohibiting multiple equilibria. Apart from its stylized geography, our model is general and allows us to provide the complete analytical characterization of equilibrium throughout the parameter space that has long eluded the literature.

Second, common theoretical approaches to the economics of cities can be usefully divided into two frameworks, classical urban economics and quantitative spatial modeling (QSM). The classical urban economics literature assumes homogenous households and stylized continuous geographies.

In contrast, QSM assumes agents with heterogeneous preferences over workplace-residence pairs; complex, empirically founded discrete geographies; and a flexible description of the first nature advantages of particular locations for work or residence. We apply a standard quantitative spatial model to a stylized geography, a discrete linear city on a featureless landscape, much like what is often studied in the classical approach. A single parameter describes household heterogeneity in our model, as in the QSM literature, and so we are able to investigate what happens as the heterogeneous households approach the homogeneity of the older urban economics literature. In this way, we unify the two literatures and allow a more complete understanding of both classes of model and their different implications for how cities behave.

While a number of our findings are surprising, two are particularly noteworthy. First, the heterogeneous preferences of the QSM framework imply that an average household must prefer central to peripheral work or residence. Such preferences have no analog in the classical literature, and they imply a concentration of work and residence in the central location even in the absence of any other agglomeration force. Second, although the set of interior equilibria is often unique, we find that corner equilibria must arise whenever there are increasing returns to scale in production. Both interior and corner equilibria always coexist as long as there are increasing returns. Our framework is similar enough to those typical of the QSM literature to suggest that these corner equilibria are a general feature of these models. Given that empirical implementations of these models typically depend on the uniqueness of equilibrium, we suspect our results may have important practical implications for this literature.

Finally, for the cities of the Western world, we present a simple and brief 500 year history of the relationships between urban form and increasing returns to scale. We then compare the qualitative features of this history with the behavior of our model as increasing returns to scale varies over a range consistent with the approximately 13-fold increase in income observed over this period. We find a qualitative relationship between the behavior we see in our model and history. Thus, our model appears to offer a simple theory that predicts the qualitative behavior of urban geography in the Western world from the pre-industrial period to the present.

2 Literature

We can usefully partition the literature into an older urban economics literature and a more recent literature on quantitative spatial models. Most papers in classical urban economics rest on the following assumptions. Households are homogenous or there are at most a small number of types. Space is continuous and uniform, whether on a line or in a plane, and equilibrium cities are generally symmetric around a single exogenously selected point. The simplest, and most influential model in this literature is the monocentric city model. It was developed by Alonso (1964), Mills (1967) and Muth (1969), and is articulated with particular clarity in Fujita (1989). This workhorse model rests on the assumption that the location of work is fixed exogenously at the center and households choose only their location of residence, although the model is otherwise quite general. In particular, firms may substitute between land and labor, and households between land and consumption.

Beckmann (1976) presents one of the earliest models to explain the endogenous formation of a city center. He assumes that household utility depends on land consumption and on the average distance to all households with which the household interacts. This leads to a city with a

bell-shaped population density distribution and a similarly shaped land rent curve. Thus, the city emerges here as a social magnet. Alternatively, in spirit of Armington (1969) where each variety of a product is differentiated by the place where it is produced, one might think of the density of social interaction between any two locations as the volume of trade between these two locations whose size decreases with distance. In this case, Beckmann’s model may be viewed as a one-dimensional reduced form of Allen and Arkolakis (2014).

The first general statement of our problem is due to Ogawa and Fujita (1980). This landmark paper considers a simple setting where firms choose only their location and households choose only their places of work and residence. They introduce the idea that firm productivity benefits from spillovers from every location, with distant spillovers less beneficial than those nearby. This assumption, now conventional, requires that the productivity of any given location responds to a distance weighted mean of employment at all locations. This creates an agglomeration externality, while land scarcity acts as a dispersion force. As the benefits of spillovers increases relative to the cost of commuting, they observe first a uniform, then a duocentric equilibrium, and finally a monocentric.

Fujita and Ogawa (1982) builds on their first paper by considering the case where spillovers decay exponentially rather than linearly with distance. When the spatial decay parameter is small, numerical results indicate that the three possible configurations described above still occur. However, when the spatial decay parameter is larger, the following may occur: (i) there exist equilibria with several centers; (ii) there is multiplicity of equilibria; and (iii) the transition from one equilibrium to another may be catastrophic. Lucas (2001) establishes general existence results in a model where agglomeration economies are not too strong and where firms and households are allowed to choose locations, subject to firms being restricted to a central business district and households to the surrounding region. Lucas and Rossi-Hansberg (2002) revisits the problem posed by Fujita and Ogawa (1982), but allow firms and households to make the same substitutions between labor and land and consumption and land as in a typical monocentric city model. They consider both constant and increasing returns to scale. They establish general existence and uniqueness results, but otherwise rely on numerical methods and restrict attention to ‘weak enough’ increasing returns that the multiple equilibria observed in Fujita and Ogawa (1982) do not arise.

Recently, a second class of models, ‘quantitative spatial models’ (QSM), has been brought to bear on problems of urban economics (Redding and Rossi-Hansberg, 2017). The fundamentals of these quantitative models are different from the older urban economics literature. In the QSM literature, model cities consist of discrete sets of locations rather than continuous spaces, and they describe realistic rather than highly stylized geographies. More importantly, this literature considers heterogenous rather than homogenous agents. The emphasis of QSM literature is also different from the older literature. Where the older literature tends to focus on analytic solutions and qualitative results, the QSM literature focuses on the numerical evaluation of particular comparative statics in models that describe particular real world locations. Examples include the fall of the Berlin wall (Ahlfeldt *et al.*, 2015) and the construction of the Transmilenio Bus Rapid Transit System in Bogota (Tsivanidis, 2019).

The QSM literature draws on a long history of scholarship on discrete choice models, and on the well-established literature that applies discrete choice models to transportation, location, geography, and trade problems (Anas, 1983; de Palma *et al.*, 1985; Tabuchi and Thisse, 2002; Eaton and Kortum, 2002). With that said, much of the recent work closely follows Ahlfeldt *et al.*

(2015).¹ In this model, households have preferences over housing and consumption, as in the older urban economics literature, and commute from home to work. Space is discrete and is described a matrix of pairwise commuting costs. These matrices are typically constructed to describe commuting costs between pairs of neighborhoods in the empirical application of interest. In the spirit of discrete choice models, households have heterogeneous preferences over work-residence pairs and each household selects a unique pair. Locations are heterogeneous in their amenities and productivity, and the possibility of endogenous agglomeration economies is sometimes considered. As a consequence of this realism, analytical results are limited. It is possible to derive analytic expressions characterizing equilibrium. There are also well-known existence results, and uniqueness has been established for the case when increasing returns are small enough to preclude multiplicity. Beyond this, most of what is known about these models results from the numerical evaluation of particular, empirically founded, comparative statics.²

3 A discrete city with heterogeneous households

A city consists of a finite set of locations \mathcal{I} with $|\mathcal{I}| = I$ and each location is endowed with one unit of land. The city is populated by a continuum $[0, 1]$ of households indexed by ν and by a competitive production sector whose size is endogenous. All households choose a residence $i \in \mathcal{I}$, a workplace $j \in \mathcal{I}$ and their consumption of housing and a tradable produced good.

Each household $\nu \in [0, 1]$ has a type $\mathbf{z}(\nu) \equiv (z_{ij}(\nu)) \in \mathbb{R}_+^{I \times I}$. Thus, a household's type is a vector of non-negative real numbers, one for each possible workplace-residence pair ij . The mapping $\mathbf{z}(\nu) : [0, 1] \rightarrow \mathbb{R}_+^{I \times I}$ is such that the distribution of types is the product measure of I^2 identical Fréchet distributions:

$$F(\mathbf{z}) \equiv \exp \left(- \sum_{i=1}^I \sum_{j=1}^I z_{ij}^{-\varepsilon} \right). \quad (1)$$

Households have heterogeneous preferences over workplace-residence pairs, and household types will parameterize these workplace-residence preferences. Thus, types describe preferences while $\varepsilon \in (0, \infty)$ describes the heterogeneity of preferences. An increase in ε reduces preference heterogeneity and conversely.

Households must commute between workplace and residence. Commuting from i to j involves an iceberg cost $\tau_{ij} \geq 1$. This cost is the same for all households and $\tau_{ij} = 1$ if and only if $i = j$. Commuting costs affect household utility directly.³

¹For example: Severen (2019); Monte *et al.* (2018); Dingle and Tintlenot (2020); Tsivanidis (2019); Couture *et al.* (2020); Balboni *et al.* (2020), Heblich *et al.* (2020), Herzog (2020) and Allen *et al.* (2016).

²Anas (1990) precedes us in efforts to unify the discrete choice framework with classical urban economics. Anas (1990) combines the monocentric city model with a finite number of colinear locations and a population of consumers who have heterogeneous tastes for housing and a composite good, described by a multinomial logit model. Anas shows that more taste heterogeneity flattens the land rent and population density gradients. Hence, the city radius expands, residential and population densities around the center decrease whereas they rise near the city edge. To put it differently, a more heterogeneous population makes the urban structure more decentralized. We will see what this result becomes when the location of production is also endogenous.

³These preferences are widely used quantitative models, e.g., Ahlfeldt *et al.* (2015), Monte *et al.* (2018) and Heblich *et al.* (2020) to mention a few. The focus on psychic rather than real commute costs can be motivated by appeal to the finding in Kahneman *et al.* (2004) that travelling between home and the workplace is reported to be one of the most unpleasant activities in individuals' daily life. Furthermore, as Redding (2020) points out, with a

A household that lives at i and works at j has utility

$$U_{ij}(\nu) = \frac{z_{ij}(\nu)}{\beta^\beta(1-\beta)^{1-\beta}} \frac{H_{ij}^\beta C_{ij}^{1-\beta}}{\tau_{ij}}.$$

where H_{ij} is household housing consumption and C_{ij} is household consumption of a homogeneous and costlessly tradable numéraire good. To simplify the model, ‘housing’ consists entirely of land.

Given the choice of workplace and residence, ij , the household budget constraint is,

$$W_j = C_{ij} + R_i H_{ij},$$

where W_j is the wage paid at location j and R_i the land rent at i . The resulting indirect utility function is

$$V_{ij}(\nu) = z_{ij}(\nu) \frac{W_j}{\tau_{ij} R_i^\beta}. \quad (2)$$

Summing up, we have a deterministic model in which each household makes mutually exclusive choices from a finite number of workplace-residence pairs ij in order to maximize their indirect utility (2).

Let

$$S_{ij} = \left\{ \mathbf{z} \in \mathbb{R}_+^{I \times I}; V_{ij}(\mathbf{z}) = \max_{r,s \in \mathcal{I}} V_{rs}(\mathbf{z}) \right\}$$

be the set of types \mathbf{z} such that ij is (weakly) preferred to all other location pairs rs . Then, using (1) and (2), the share s_{ij} of households who choose the location pair ij equals

$$s_{ij} = \mu(\mathbf{z}^{-1}(S_{ij})) = \frac{\left[W_j / (\tau_{ij} R_i^\beta) \right]^\varepsilon}{\sum_{r \in \mathcal{I}} \sum_{s \in \mathcal{I}} \left[W_s / (\tau_{rs} R_r^\beta) \right]^\varepsilon}, \quad (3)$$

where the last equality stems from the Fréchet distribution assumption and μ is the Lebesgue measure over $[0, 1]$.⁴ Our model is static and so all choices occur simultaneously.

Because the $V_{ij}(\nu)$ are Fréchet distributed, the average utility \bar{V} across all households equals:

$$\bar{V} \equiv \int_0^1 \max_{i,j=1,\dots,I} V_{ij}(\mathbf{z}(\nu)) d\nu = \Gamma\left(\frac{\varepsilon-1}{\varepsilon}\right) \left\{ \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{I}} \left[W_j / (\tau_{ij} R_i^\beta) \right]^\varepsilon \right\}^{1/\varepsilon},$$

where $\Gamma(\cdot)$ is the gamma function.⁵ Households that share the same type choose the same location pair⁶ ij and reach the same equilibrium utility level, while households who make the same choice may have different types and do not have the same equilibrium utility level. Likewise,

linear homogenous utility function this formulation is equivalent to one in which the budget is $W_j/z_{ij} = C_{ij} + R_i H_{ij}$ and z_{ij} does not appear directly in the utility function. This equivalence also requires that the taste parameters do not enter the market clearing condition for land.

⁴Note that there might be types which belong to more than one S_{ij} as they are indifferent between their multiple favorite choices. However, the set of such types always has a zero measure, so that they do not affect the type distribution (1).

⁵For the average utility to be finite, we require $\varepsilon > 1$.

⁶Except for the measure zero set of types that is indifferent between alternatives.

households that choose different location pairs do not generally enjoy the same equilibrium utility level. In general, equilibrium utility varies with type.

In the QSM based literature, locations are typically endowed with both employment and residential ‘amenities’ that scale the payoffs from work and residence in each location. While it is straightforward to incorporate these terms into our model, we omit them for two reasons. First, it eases notation. More importantly, it restricts our QSM based model to a stylized, featureless landscape of the sort considered in classical urban economics, and thereby facilitates the comparison of the two literatures.

We have described an explicitly static and deterministic model of heterogeneous households. Existing formulations of this model are less clear about this issue. This can lead to questions about households’ expectations and the extent to which those expectations coincide with realized outcomes.⁷ Such questions are usually resolved by informal appeals to the law of large numbers, despite the difficulty of formulating the law of large numbers for a continuum (Judd, 1985; Feldman and Gilles, 1985; Uhlig, 1996). By insisting on a deterministic model of heterogeneous households, we avoid these (admittedly subtle) issues. There is no need for probabilities and expectations; our outcomes are shares and averages.

We can rewrite (3) as,

$$s_{ij} = \kappa R_i^{-\beta\epsilon} W_j^\epsilon \tau_{ij}^{-\epsilon}, \quad (4)$$

for

$$\kappa \equiv \left[\Gamma \left(\frac{\epsilon - 1}{\epsilon} \right) \right]^\epsilon \bar{V}^{-\epsilon}. \quad (5)$$

Let M_i and L_i be the mass of residents and households at i . Labor and land market clearing requires

$$\sum_{i \in \mathcal{I}} L_i = \sum_{j \in \mathcal{I}} M_j = 1, \quad (6)$$

where the residential population at i is

$$M_i \equiv \sum_{j \in \mathcal{I}} s_{ij} = \kappa R_i^{-\beta\epsilon} \sum_{j \in \mathcal{I}} W_j^\epsilon \tau_{ij}^{-\epsilon}, \quad (7)$$

while the labor force at j is

$$L_j \equiv \sum_{i \in \mathcal{I}} s_{ij} = \kappa W_j^\epsilon \sum_{i \in \mathcal{I}} R_i^{-\beta\epsilon} \tau_{ij}^{-\epsilon}. \quad (8)$$

Because each location i is endowed with one unit of land, land market clearing requires

$$(H_i + N_i - 1)R_i = 0, \quad (9)$$

where H_i is the amount of residential land and N_i is the amount of commercial land at location i . Condition (9) implies that land rent is zero when the whole amount of land at i is not used. In particular, it allows for corner equilibria in which $H_i^* = N_i^* = 0$ at some location i .

Applying Roy’s identity to (2), we have

$$H_i \equiv \sum_{j \in \mathcal{I}} s_{ij} H_{ij} = \sum_{j \in \mathcal{I}} s_{ij} \frac{\beta W_j}{R_i}. \quad (10)$$

⁷These issues are stated clearly in Dingle and Tintlenot (2020).

Substituting from (4) gives

$$R_i = \left(\frac{\beta\kappa}{H_i} \sum_{j \in \mathcal{I}} W_j^{1+\varepsilon} \tau_{ij}^{-\varepsilon} \right)^{\frac{1}{1+\beta\varepsilon}}. \quad (11)$$

This is the bid rent that households are willing to pay to reside at i , given (W_1, \dots, W_I, H_i) . Land rent accrues to absentee landlords who play no further role in the model.

Assume that the numéraire is produced under perfect competition while the production function at location j is

$$Y_j = A_j L_j^\alpha N_j^{1-\alpha},$$

where A_j is location-specific TFP and $0 < \alpha < 1$. We assume that A_j depends only on the level of employment at j ,

$$A_i = L_i^\gamma, \quad (12)$$

for $\gamma \geq 0$, which is the same for all i .

Our description of returns to scale restricts attention to local scale economies. This is common in the literature and is consistent with empirical evidence that knowledge and information spillovers are localized because they arise mainly through face-to-face contacts (Arzaghi and Henderson, 2008; Ahlfeldt *et al.*, 2015; Liu *et al.*, 2018; Battiston *et al.*, 2021). We do not allow for spillovers of the sort that form the basis for important previous work such as Ogawa and Fujita (1980) or Lucas (2000). In fact, we have investigated this more general description of urban productivity. Preliminary efforts indicate that extending our analysis to permit such spillovers suggests that the model behaves in much the same way as the one we analyze here. With that said, the notational burden of the more general formulation is heavy. While we regard such generalizations of our model as an interesting topic for further research, for the purpose of investigating the effects of returns to scale on urbanization, we prefer our simpler description of production and returns to scale.

If location j hosts a positive share of the production sector, the first-order conditions for the production sector yields the equilibrium wage and land rent as functions of land-labor ratio:

$$W_j = \alpha A_j \left(\frac{N_j}{L_j} \right)^{1-\alpha}, \quad (13)$$

$$R_j = (1 - \alpha) A_j \left(\frac{L_j}{N_j} \right)^\alpha. \quad (14)$$

Dividing (13) by (14) and simplifying,

$$\frac{W_j}{R_j} = \frac{\alpha}{1 - \alpha} \frac{N_j}{L_j}. \quad (15)$$

When $\gamma = 0$, note that

$$R_j = (1 - \alpha) \left(\frac{N_j}{L_j} \right)^{-\alpha} = (1 - \alpha) \left(\frac{W_j}{\alpha} \right)^{-\alpha/(1-\alpha)}. \quad (16)$$

This expression implies that R_j and W_j move in opposite directions under constant returns: a higher land rent at j is equivalent to a lower wage at this location. Moreover, the land rent at j is positive and finite if and only if W_j is positive and finite.

Our city is described by I -vectors of real numbers. To describe them, define a *spatial pattern* to be an element of \mathbb{R}_+^I , a vector enumerating a non-negative real number for each location in \mathcal{I} . The spatial patterns that describe our model city are: the *residential pattern* $\mathbf{M} \equiv (M_1, M_2, \dots, M_I)$; the *employment pattern* $\mathbf{L} \equiv (L_1, L_2, \dots, L_I)$; the *housing pattern* $\mathbf{H} \equiv (H_1, H_2, \dots, H_I)$; the *commercial pattern* $\mathbf{N} \equiv (N_1, N_2, \dots, N_I)$; the *wage pattern* $\mathbf{W} \equiv (W_1, W_2, \dots, W_I)$; and the *land rent pattern* $\mathbf{R} \equiv (R_1, R_2, \dots, R_I)$. A spatial pattern is *interior* if none of its elements is zero. Otherwise, it is called a *corner* pattern.

We are now able to provide a precise definition of an equilibrium for our discrete city with heterogenous agents.

Definition 1 A (spatial) equilibrium is a vector $\{\mathbf{M}^*, \mathbf{L}^*, \mathbf{H}^*, \mathbf{N}^*, \mathbf{W}^*, \mathbf{R}^*\}$ such that:

- i. all households make utility-maximizing choices of workplace, residence, land, and consumption to satisfy (3),
- ii. the first-order conditions (13) and (14) are satisfied at every location where the tradable good is produced,
- iii. the condition (9) holds at each location, and
- iv. the population constraint (6) holds.

An equilibrium is *interior* when all components of the vector $\{\mathbf{M}^*, \mathbf{L}^*, \mathbf{H}^*, \mathbf{N}^*, \mathbf{W}^*, \mathbf{R}^*\}$ are positive. Otherwise, we have a *corner* equilibrium in which some locations host no residents, no workers, or both. Note that (ii) of the above definition allows for corner equilibria in which there is no production at some location ($L_i^* = W_i^* = 0$), and we will see in Proposition 4 that such equilibria are common. On the other hand, the following proposition establishes the impossibility of equilibria where any location has zero residence.

Proposition 1 For all equilibria, $H_i^* > 0$ and $R_i^* > 0$ at each location $i \in \mathcal{I}$.

Proof: The argument involves two steps. First, it follows from (13) that $W_j^* = 0$ when the tradable good is not produced at location j because $L_j^* = N_j^* = 0$. Since there is at least one location $j \in \mathcal{I}$ that hosts a strictly positive mass of workers, $A_j = L_j^\gamma > 0$ for all $\gamma \geq 0$. As a result, firms' demand for labor at j is infinite while the labor supply is finite, a contradiction. Second, assume that $R_i^* = 0$ at i . Since there is a location $j \in \mathcal{I}$ such that $W_j^* > 0$, workers who choose the pair ij enjoys an infinite utility level, which implies $s_{ij} > 0$. These workers' land demand is thus infinite while the land supply is finite, a contradiction. Q.E.D.

4 A linear city with three locations

Our discrete city with heterogenous households is based on assumptions and functional forms common in the QSM literature. Because the object of the QSM literature is (usually) the numerical evaluation of particular empirically founded comparative statics, this means that our model is more complex than we require to investigate analytic comparative statics or to compare with the more stylized urban economics literature. Therefore, we let $\mathcal{I} \equiv \{-1, 0, 1\}$ and restrict our discrete city with heterogenous agents to a geography consisting of three identical locations evenly spaced along a line.

This geography is the simplest in which to examine when activities concentrate in the center or disperse to the periphery. Thus, it is the simplest geography in which we can consider when a city forms a central district where activity is concentrated, and when economic activity remains dispersed. It is also qualitatively similar to the geography of the linear monocentric city that forms the basis for much of the urban economics literature.

For tractability and to ease comparison with the urban economics literature, we focus on *symmetric spatial patterns* $x = (x_{-1}, x_0, x_1)$ where $x_1 = x_{-1}$, and usually write such patterns as (x_1, x_0, x_1) rather than (x_{-1}, x_0, x_1) . We say that a symmetric spatial pattern is *bell-shaped*, *flat*, or *U-shaped* as x_0 is greater than, equal to, or less than x_1 . Say that a symmetric spatial pattern (x_1, x_0, x_1) is *more centralized* than a symmetric spatial pattern (y_1, y_0, y_1) if and only if $\frac{x_0}{x_1} > \frac{y_0}{y_1}$.

The restriction to three locations and symmetric patterns, allows us to focus our attention on the symmetric, three element versions of the spatial patterns listed above: (M_1, M_0, M_1) , (L_1, L_0, L_1) , (H_1, H_0, H_1) , (N_1, N_0, N_1) , (W_1, W_0, W_1) , and (R_1, R_0, R_1) . That is, the patterns for residence, employment, housing, industry, wages and land rents.

Our analysis below is organized around studying the centrality of these six patterns. To facilitate this, define the corresponding centrality ratios,

$$m \equiv \frac{M_0}{M_1}; \quad \ell \equiv \frac{L_0}{L_1}; \quad h \equiv \frac{H_0}{H_1}; \quad n \equiv \frac{N_0}{N_1}; \quad w \equiv \frac{W_0}{W_1}; \quad r \equiv \frac{R_0}{R_1}.$$

Under symmetry, given an aggregate constraint, e.g. $2x_1 + x_0 = 1$, a spatial pattern is uniquely determined by one more piece of information, such as the ratio x_0/x_1 .

For this linear city, the iceberg commuting cost matrix is

$$\begin{pmatrix} \tau_{-1,-1} & \tau_{-1,0} & \tau_{-1,1} \\ \tau_{0,-1} & \tau_{0,0} & \tau_{0,1} \\ \tau_{1,-1} & \tau_{1,0} & \tau_{1,1} \end{pmatrix} = \begin{pmatrix} 1 & \tau & \tau^2 \\ \tau & 1 & \tau \\ \tau^2 & \tau & 1 \end{pmatrix}, \quad (17)$$

where $\tau > 1$. To ease notation, we define

$$\begin{aligned} a &\equiv \frac{\alpha\beta}{1-\alpha} > 0, \\ b &\equiv \frac{(1-\alpha)(1+\varepsilon)}{\alpha\beta\varepsilon} = \frac{1+\varepsilon}{a\varepsilon}, \\ \phi &\equiv \tau^{-\varepsilon}. \end{aligned} \quad (18)$$

The parameter a is important enough for our analysis to merit discussion. Recall that α and β are the labor share of output and the housing share of consumption. Thus, the denominator of a is the commercial land share and the numerator is the induced residential land share in production. It follows that a measures the relative intensity of the production sector's demand for commercial versus residential land. As a increases, firms are relatively less reliant on commercial land, and conversely. Recalling that the periphery is land rich and the center is land poor, it is not surprising that a plays an important role in determining whether employment or residence is more centralized.

We will sometimes refer to $\phi \in (0, 1)$ as the *spatial discount factor*. By inspection of equation (18), ϕ decreases with the level of commuting costs ($\tau \uparrow$) and increases with the heterogeneity of the population ($\varepsilon \downarrow$). Hence, ϕ may be large (resp., low) because either commuting costs are low (resp., high), or the population is very (resp., not very) heterogeneous, or both.⁸

Applying the symmetry assumption to the wage and land rent patterns \mathbf{W} and \mathbf{R} and using (4) and (17), we get the following equilibrium conditions:

$$\begin{aligned} s_{0,0} &= \kappa R_0^{-\beta\varepsilon} W_0^\varepsilon, \\ s_{0,1} &= s_{0,-1} = \kappa R_0^{-\beta\varepsilon} W_1^\varepsilon \tau^{-\varepsilon}, \\ s_{1,1} &= s_{-1,-1} = \kappa R_1^{-\beta\varepsilon} W_1^\varepsilon, \\ s_{1,-1} &= s_{-1,1} = \kappa R_1^{-\beta\varepsilon} W_1^\varepsilon \tau^{-2\varepsilon}, \\ s_{1,0} &= s_{-1,0} = \kappa R_1^{-\beta\varepsilon} W_0^\varepsilon \tau^{-\varepsilon}. \end{aligned} \tag{19}$$

Setting

$$\omega \equiv w^\varepsilon \quad \text{and} \quad \rho \equiv r^{-\beta\varepsilon}, \tag{20}$$

the first-order condition (16) becomes $\rho = \omega^a$. Clearly, $\omega > 1$ means that jobs at the central area pay a higher wage than those at the peripheries, while $\rho > 1$ means that land at the central area is cheaper than that at the peripheries.

We can now discuss the economic forces at work in this model. To illustrate ideas, consider the case when wages and land rents are the same in all locations and the resulting indirect utility is $V_{ij} = V$. In this case, using (2), a household's discrete choice problem is

$$\max_{ij} \left\{ \begin{array}{ccc} z_{-1,-1}V, & \frac{z_{-1,0}}{\tau}V, & \frac{z_{-1,1}}{\tau^2}V \\ \frac{z_{0,-1}}{\tau}V, & z_{0,0}V, & \frac{z_{0,1}}{\tau}V \\ \frac{z_{1,-1}}{\tau^2}V, & \frac{z_{1,0}}{\tau}V, & z_{1,1}V \end{array} \right\}.$$

This is the standard way of stating a discrete choice problem, except that we have arranged the nine choices in a matrix so that the row choice corresponds to a choice of residence and choice of column to a choice workplace.

In this case, because the distribution of idiosyncratic tastes is identical for all nine location pairs, the average payoff for a household choosing a central residence is

$$E \left(\max \left\{ \frac{z_{0,-1}}{\tau}V, z_{0,0}V, \frac{z_{0,1}}{\tau}V \right\} \right) = \Gamma \left(\frac{\varepsilon - 1}{\varepsilon} \right) \left(1 + \frac{2}{\tau^\varepsilon} \right)^{1/\varepsilon} V. \tag{21}$$

⁸It is common in the trade and geography literature with CES monopolistic competition to use a spatial discount factor defined by $\phi \equiv \tau^{-\sigma}$ where σ is the elasticity of substitution of the CES utility function and τ the trade cost. This spatial discount factor does not differ much from ours. Indeed, we know from the relationship between the CES and the MNL that $\mu = \sigma - 1$ where $\mu > 0$ decreases with the heterogeneity of the population (Anderson *et al.*, 1992). Therefore, a lower σ may be interpreted as a more heterogeneous population, much like a lower ε .

Similarly, the average payoff for a household choosing one of the peripheral locations as a residence is

$$E \left(\max \left\{ z_{-1,-1} V, \frac{z_{-1,0}}{\tau} V, \frac{z_{-1,1}}{\tau^2} V \right\} \right) = \Gamma \left(\frac{\varepsilon - 1}{\varepsilon} \right) \left(1 + \frac{1}{\tau^\varepsilon} + \frac{1}{\tau^{2\varepsilon}} \right)^{1/\varepsilon} V. \quad (22)$$

Because $\tau > 1$, it follows that the average payoff for a household choosing the peripheral location is lower than that of an average household choosing the central location. By symmetry, the corresponding statement is also true for the choice of work location. As a result, the average payoff for a household choosing a peripheral work location is lower than that of an average household choosing the central location for work. In this sense, the structure of the above discrete choice problem creates what we will call an *average preference* for residence in the central location, and a similar average preference for work in the central location. Note that the intensity of preference for central location also depends on the commuting cost τ and the population heterogeneity ε .

This is noteworthy for the following reasons. First, even in the absence of more familiar agglomeration effects operating through production, this model has *two* ‘agglomeration’ forces, the average preference for central work and the average preference for central residence. Second, these average preferences are not agglomeration forces in the conventional sense. They do not incentivize geographic concentration, rather they incentivize concentration in the central location. Third, the urban economics literature based on homogenous agents takes seriously the possibility of differential labor productivity across locations. However, the possibility of *preferences* over work locations is never considered. This is a feature of quantitative spatial models without analog in the urban economics literature. Fourth, on the basis of the existing literature, we expect that the preference for central residence will be capitalized into higher central land rents. We will see that the preference for central work location will be reflected in lower wages.

Against the two centralizing forces of average preferences are set two centrifugal forces. There is twice as much land in the periphery as the center. Because land contributes to utility and productivity, the scarcity of central land incentivizes the movement of employment and residence to the periphery.

We can now guess at the form of a symmetric equilibrium under constant returns to scale. In equilibrium, the centrifugal force of land scarcity and the centralizing force of average preferences balance. Access to the center will be scarce and so land rent will be higher and wages lower in the center. Whether the center ends up relatively specialized in residence or work will depend on which of the two activities has the highest demand for land, and this activity will locate disproportionately in the land abundant periphery.

We postpone a discussion of equilibrium under increasing returns to scale until after we provide a more formal characterization of such equilibria.

5 Existence of equilibria

We now turn to the characterization of symmetric equilibria in our three location city. We proceed in three main steps. In the first, we derive the demand for housing, the demand for commercial space, the supply of workers, and the supply of residents as functions of ω and ρ . This

done, we derive a system of two equations in wages and land rent that characterize equilibrium. In the third step, we solve this system of equations.

The next proposition shows that in equilibrium all variables can be expressed in terms of just ρ and ω .

Proposition 2 *The equilibrium demand for housing and commercial space and the equilibrium supply of workers and residents are:*

$$M_0 = \frac{\rho(\omega + 2\phi)}{\rho(\omega + 2\phi) + 2(\phi\omega + 1 + \phi^2)}, \quad M_1 = \frac{1 - M_0}{2}, \quad (23)$$

$$L_0 = \frac{\omega(\rho + 2\phi)}{\omega(\rho + 2\phi) + 2(\phi\rho + 1 + \phi^2)}, \quad L_1 = \frac{1 - L_0}{2}, \quad (24)$$

$$H_0 = \frac{a\rho(1 + 2\phi\omega^{-\frac{1+\varepsilon}{\varepsilon}})}{a\rho(1 + 2\phi\omega^{-\frac{1+\varepsilon}{\varepsilon}}) + \rho + 2\phi}, \quad N_0 = 1 - H_0, \quad (25)$$

$$H_1 = \frac{a(\phi\omega^{\frac{1+\varepsilon}{\varepsilon}} + 1 + \phi^2)}{a(\phi\omega^{\frac{1+\varepsilon}{\varepsilon}} + 1 + \phi^2) + \phi\rho + 1 + \phi^2}, \quad N_1 = 1 - H_1. \quad (26)$$

Proof: See Appendix A.

The derivation of these functions involves algebraic manipulation of the equilibrium conditions. For example, each of M_i and L_j is derived from the expressions for the share of households choosing each workplace-residence pair ij . In one case, we sum over workplace-residence pairs with a common residence, and in the other over pairs with a common workplace. The identical denominator for each of the four functions is simply the three-location version of the denominator on the right-hand side of equation (3). The expressions for H_i and N_j are more complicated because they must also satisfy the land market clearing condition (9). Notice that we write M_i , L_i , N_j , and H_i exclusively in terms of price ratios, r and w , rather than the prices themselves, R_i and W_j . This simplifies our effort to characterize equilibrium because we need to solve for only two equilibrium quantities instead of four.

The functions described in Proposition 2 permit the straightforward evaluation of comparative statics. For example, when the relative land price at the center decreases (ρ increases), central residents and their land consumption (M_0 and H_0) both increase, with opposite effects in the periphery. Similarly, a decrease in ρ implies an increase in central employment, L_0 , and a decrease in N_0 as the production sector substitutes away from relatively expensive central land toward relatively inexpensive central labor and peripheral land. An increase in ω requires an increase in the ratio of the central to the peripheral wage and has an effect similar to a decrease in ρ . As ω increases, the relative wage at the center increases. As this happens, L_0 decreases, N_0 increases and H_0 increases, i.e., the production sector substitutes land for labor and households consume more land. Effects in the periphery are opposite. These comparative statics do not depend on the values of the structural parameters α , β , γ , ε , and τ .

We now turn to finding the equilibrium values of ω and ρ . We would like to derive a system of equations involving only ω and ρ that incorporates all of the equilibrium conditions given in definition 1. The following proposition describes such a system.

Proposition 3 *Assume $\gamma \neq \alpha/\varepsilon$. Then, a pair (ρ^*, ω^*) is an interior equilibrium if and only if it solves the following two equations:*

$$\omega^{\frac{1+\varepsilon}{\varepsilon}} = f(\rho) \equiv \frac{\phi\rho - 2a\phi\rho^{1+\frac{1}{\beta\varepsilon}} + (1+\phi^2)(1+a)}{(1+a)\rho^{1+\frac{1}{\beta\varepsilon}} + 2\phi\rho^{\frac{1}{\beta\varepsilon}} - a\phi}, \quad (27)$$

$$\omega^{\frac{1+\varepsilon}{\varepsilon}} = g(\rho; \gamma) \equiv \rho^{\frac{b}{1-\gamma\varepsilon/\alpha}} \left(\frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} \right)^{\frac{\gamma\varepsilon/\alpha}{1-\gamma\varepsilon/\alpha} \frac{1+\varepsilon}{\varepsilon}}. \quad (28)$$

Proof: See Appendix B.

Combining (27) and (28), we arrive at a single equation in terms ρ , that determines the interior equilibria. Thus, studying the equilibrium behavior of our discrete linear city reduces to studying the solution(s) of one equation in one variable:

$$f(\rho) = g(\rho; \gamma). \quad (29)$$

We show the existence of an interior equilibrium by showing that (29) has a positive solution ρ^* . We determine the number of possible interior equilibria by determining the number of positive solutions of equation (29).

This argument requires two comments. First, equation (29) is not defined when $\gamma = \alpha/\varepsilon$, so that we will need a specific argument for this case. Second, we will see that $\gamma = \alpha/\varepsilon$ is a threshold value of γ , below which equilibrium is unique, and above which multiple equilibria may emerge. To ease exposition of equilibrium behavior around this threshold, define $\gamma_m \equiv \alpha/\varepsilon$.

We now turn to a characterization of equilibrium. To begin, we establish the properties of the functions f and g . Observe that the function f does not involve the parameter γ , and thus remains the same for all values of γ . The following lemma states the main properties of function the f that are important for the characterization of spatial equilibria.

Lemma 1 *The function $f(\rho)$ has a vertical asymptote at $\rho = \rho_0 \in (0, 1)$, decreases over (ρ_0, ρ_1) and is equal to 0 at $\rho = \rho_1 > 1$, while $f(\rho) < 0$ for $\rho \notin [\rho_0, \rho_1]$.*

Proof: See Appendix C.

Unlike f , the function g varies with γ . We show in Lemma 2 that when $\gamma < \gamma_m$, g is an increasing function that converges to an increasing step function as $\gamma \nearrow \gamma_m$. When $\gamma > \gamma_m$, g is a decreasing function that converges to a step function as $\gamma \searrow \gamma_m$. In both limiting cases, the value ρ_L at which the step occurs solves

$$\rho^{\frac{1}{a}} \frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} = 1. \quad (30)$$

Because the left-hand side of (30) increases with ρ and is equal to 0 (resp., ∞) when $\rho = 0$ (resp., $\rho \rightarrow \infty$), ρ_L is unique and $\rho_L < 1$.

The following lemma provides a more formal statement of the relevant properties of g .

Lemma 2 (i) If $\gamma \neq \gamma_m$, then $g(\rho; \gamma)$ is strictly positive and finite over $[\rho_0, \rho_1]$. (ii) If $\gamma < \gamma_m$, then g is increasing over $[\rho_0, \rho_1]$. (iii) If $\gamma > \gamma_m$, then g is decreasing over $[\rho_0, \rho_1]$. (iv) As γ converges to γ_m , we have:

$$\lim_{\gamma \nearrow \gamma_m} g(\rho; \gamma) = \begin{cases} 0, & \rho < \rho_L; \\ \left(\frac{\rho_L + 2\phi}{\phi \rho_L + 1 + \phi^2} \right)^{-\frac{1+\varepsilon}{\varepsilon}}, & \rho = \rho_L; \\ \infty, & \rho > \rho_L; \end{cases} \quad \lim_{\gamma \searrow \gamma_m} g(\rho; \gamma) = \begin{cases} \infty, & \rho < \rho_L; \\ \left(\frac{\rho_L + 2\phi}{\phi \rho_L + 1 + \phi^2} \right)^{-\frac{1+\varepsilon}{\varepsilon}}, & \rho = \rho_L; \\ 0, & \rho > \rho_L. \end{cases}$$

Proof: Part (i) follows from combining (28) with $0 < \rho_0 < \rho_1 < \infty$. Parts (ii) and (iii) are obtained by differentiating g with respect to ρ . Part (iv) holds because $g(\rho; \gamma)$ may be rewritten as follows:

$$g(\rho; \gamma) = \left[\left(\rho^{\frac{1}{a}} \frac{\rho + 2\phi}{\phi \rho + 1 + \phi^2} \right)^{\frac{\gamma_m}{\gamma_m - \gamma}} \cdot \left(\frac{\rho + 2\phi}{\phi \rho + 1 + \phi^2} \right)^{-1} \right]^{\frac{1+\varepsilon}{\varepsilon}}. \quad (31)$$

Q.E.D.

The four panels of figure 1 illustrate the functions f and g for various parameter values. In each panel, the horizontal axis is ρ and the vertical axis is an increasing transformation of ω . The behavior of f , the red line in each panel, is relatively simple. It is a decreasing, continuous function that has a positive asymptote at $\rho_0 < 1$ and declines monotonically to 0 at $\rho_1 > 1$. The behavior of g is more complicated. The two panels on the left each describe g for three different values of γ , with dark blue the smallest, light blue the largest, medium blue in between, and all three less than γ_m . In every case, g is a continuous, increasing function. The right column is the same as the left, but considers larger values of γ . Here, the light blue line traces g for the smallest value of γ , dark blue uses the largest value, medium blue is intermediate value, and all three are greater than γ_m .

This figure makes clear that, in general, f and g cross for a positive value ρ , and when $\gamma > \gamma_m$, they may cross more than once. On this basis, we can surmise that an equilibrium exists in our model city throughout much or all of the parameter space.

So far, we have focused on interior equilibria. The following proposition states a necessary and sufficient condition for all equilibria to be interior and characterizes the corner equilibria that arise when this condition does not hold.

Proposition 4 If $\gamma \geq 0$, an interior equilibrium always exists. Furthermore, there exist corner equilibria if and only if $\gamma > 0$. These corner equilibria are given by $L_0^* = 1$ and $L_1^* = 1/2$.

Proof: Using the properties of f and g given in Lemmas 1 and 2, the intermediate value theorem implies the existence of an equilibrium when $\gamma \neq \gamma_m$. The case where $\gamma = \gamma_m$ is considered in Propositions 7 and 8. We show in Appendix D that there exist two corner equilibria for all $\gamma > 0$: (i) $\omega^* \rightarrow \infty$ and $\rho^* = \rho_1$, and thus employment is evenly distributed between peripheries, and (ii) $\omega^* = 0$ and $\rho^* = \rho_0$, so that employment is fully concentrated at the center $i = 0$. Q.E.D.

Multiple equilibria arise immediately once there are increasing returns. Given multiple equilibria, it is commonplace to appeal to stability as a selection device. Informally, we will say that an

equilibrium of the economy is stable if, after a small perturbation of ρ , it returns to the same steady state. In appendix F we show that an equilibrium satisfies this definition if f crosses g from above. We note that this definition of stability is fundamentally indeterminate. Also informally, to apply this definition we must choose the direction in which time must run. This choice is arbitrary and results in opposite conclusions about the stability of any given steady state. We resolve this indeterminacy so that the unique equilibrium under constant returns to scale and the unique interior equilibrium under weak increasing returns are both stable. We discuss this issue further in appendix F.

Before we begin the analysis of the comparative statics of our model, we derive the relationship between land rent and employment. This relationship is surprisingly simple and will be useful in a number of our proofs. Using (24) leads to

$$\ell = \omega \frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2}.$$

Combining this with (28), this equation becomes

$$\ell = \left(\rho^{\frac{1}{a}} \frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} \right)^{\frac{\gamma_m}{\gamma_m - \gamma}}. \quad (32)$$

If $\gamma < \gamma_m$, then ℓ increases over (ρ_0, ρ_1) and $\ell(\rho) > 1$ if and only if $\rho > \rho_L$. On the other hand, when $\gamma > \gamma_m$, the opposite holds: ℓ decreases over (ρ_0, ρ_1) and $\ell(\rho) > 1$ if and only if $\rho < \rho_L$.

6 Comparative statics

We now turn our attention to an investigation of how the equilibrium behavior of our city changes as fundamental characteristics of the economy change. More specifically, we focus on the implications of changes in returns to scale, γ , commuting costs, τ , and preference dispersion, ε .

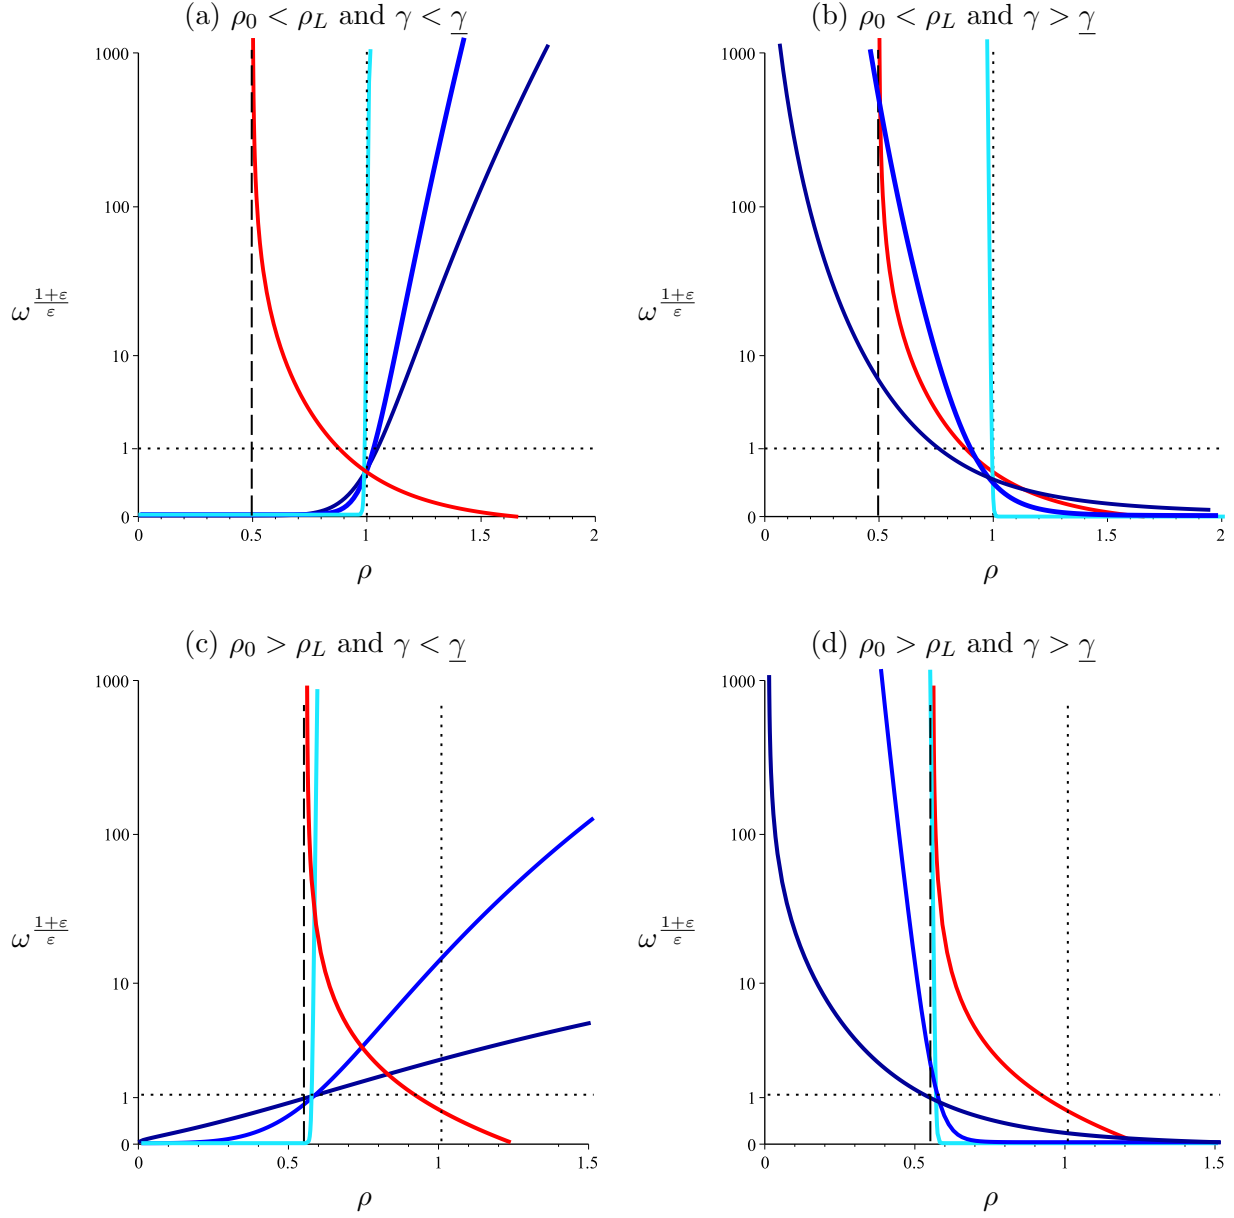

6.1 Returns to scale

Lemma 1 shows that f has an asymptote at $\rho_0 < 1$ and is zero at $\rho_1 > 1$. Lemma 2 shows that as $\gamma \rightarrow \gamma_m$, g also approaches its asymptote at $\rho_L < 1$. While Lemmas 1 and 2 guarantee that $\rho_1 > \rho_L$, they do not allow us to order ρ_L and ρ_0 . Unsurprisingly, the equilibrium configuration of our city depends sensitively on whether or not $\rho_L > \rho_0$. As a precursor to our analysis of changes in γ , Lemma 3 provides necessary and sufficient conditions on commuting costs and the demands for commercial and residential land for $\rho_L > \rho_0$.

Lemma 3 *There exists a function $\bar{\phi}(\beta, \varepsilon) \in (0, 1)$ and scalar $\bar{a} > 0$ such that if $\phi < \bar{\phi}$ or $a < \bar{a}$ then $\rho_0 < \rho_L$. Conversely, if $\phi > \bar{\phi}$ and $a > \bar{a}$ then $\rho_0 > \rho_L$.*

Proof: See Appendix E.

Figure 1: Graphical demonstration of equilibrium for a range of parameter values.

Notes: These figures illustrate equilibrium in several different cases. In all panels, f is given by the red line. The blue lines describe g . In the left two panels, darker colors of blue indicate smaller values of γ and in the right two panels darker colors of blue indicate larger values of γ .

Restating this lemma informally, we have $\rho_0 < \rho_L$ if either the spatial discount factor is low *or* the demand for commercial land is sufficiently large relative to the demand for residential land. Conversely, if the spatial discount factor is high *and* the demand for commercial land is low, then $\rho_0 > \rho_L$.

We now investigate changes in the equilibrium behavior of our city as returns to scale changes. To

ease exposition, we introduce terminology to describe the three important domains of return to scale. These ranges will correspond to qualitatively different equilibrium behavior.

Definition 2 *Increasing returns to scale (IRS) are:*

- i. *weak* $\Leftrightarrow 0 < \gamma < \gamma_m$,
- ii. *moderate* $\Leftrightarrow \gamma_m < \gamma < \gamma_s$,
- iii. *strong* $\Leftrightarrow \gamma > \gamma_s$, where $\gamma_s \in (\gamma_m, \frac{1+\varepsilon}{(1-\beta)\varepsilon} - \alpha]$.

Production is constant returns to scale when $\gamma = 0$.

This definition requires two comments. First, population must be heterogeneous (ε finite) for weak returns to scale to occur. Hence, the behavior we observe in this domain of the parameter space cannot arise in models with the homogenous households that are standard in the urban economics literature. Second, these definitions indicate that the parameters α , β and γ are not sufficient to determine the regime to which the economy belongs. This also depends on ε . Because equilibrium behavior varies qualitatively with the type of returns to scale, it follows that qualitative features of the equilibrium outcome depend on the degree of preference heterogeneity.⁹

Figure 1 summarizes Lemmas 1-3 graphically. The top two panels describe cities where $\rho_0 < \rho_L$, a city where commuting costs are high or land is valuable in production. The bottom two panels describe an economy where $\rho_0 > \rho_L$, a city where commuting costs are low and land has a low value in production. The two panels on the left describe cities where production involves constant or weak increasing returns to scale. The right two panels describe cities where increasing returns are moderate or strong. Each panel evaluates g for three different values of γ . In every panel, the light blue line describes g for a value of γ close to the weak/moderate threshold γ_m , and darker blue lines describe g functions for values of γ that are progressively further from this threshold, smaller in panels (a) and (c) and larger in panels (b) and (d). Taken together, these figures permit a fairly complete, if informal, description of the interior equilibria of our linear city with three locations.

Begin with the case of constant or weak increasing returns to scale illustrated in panels (a) and (c). In panel (a), $\rho_0 < \rho_L$ so that high commuting costs encourage households to work where they live or land hungry production faces pressure to disperse to the periphery (or both). We expect an equilibrium in such an economy to exhibit low levels of commuting and dispersed production. In fact, regardless of γ , f and g cross near $\rho = 1$ and at a moderate value of ω . Since $\rho_0 < \rho_L$, as $\gamma \nearrow \gamma_m$ and g approaches its asymptote at ρ_L , it does so when f is well away from its asymptote at ρ_0 . Hence, the equilibrium value of ω is relatively low. In this economy, the ratio of central to peripheral wages can never grow too large. Thus, panel (a) describes a city where employment and residence are not highly concentrated in the center or the periphery.

In contrast, panel (c) shows an economy where $\rho_L < \rho_0$. In this economy, low commuting costs allow households to separate work and residence locations in response to a small wage premium,

⁹This concurs with models of spatial competition models where firms locations depend on the degree of consumer heterogeneity (Anderson *et al.*, 1992, ch.7).

and productivity is not sensitive to the relatively abundant land of the periphery. In such an economy, we expect that increasing returns to scale compounds the average preference for central employment to concentrate employment in the center, and that households are able to cheaply disperse their residences to the land abundant periphery. In this city, as γ approaches γ_m , it does so near the asymptote of f . As a result, the value of ω at which the two curves intersects becomes large. This reflects that fact that peripheral productivity is falling almost to zero as production concentrates in the center and consumes progressively less peripheral land, even as central productivity rises with agglomeration economies. Panel (c) describes a city where commuting costs are low enough and the centrifugal forces on production weak enough for the average preference for central employment and increasing returns to scale complement each other to concentrate employment in the center.

Propositions 5, 6 and 7, presented below, formalize and refine this intuition about equilibrium with constant returns to scale or weak increasing returns to scale, and establish its generality.

Panels (b) and (d) of Figure 1 illustrate equilibria with moderate or strong increasing returns. As returns to scale increase beyond γ_m , behavior becomes more complicated. In panel (b) we again consider the city where $\rho_0 < \rho_L$ so that commuting is costly or land has a relatively high return in production. To begin, consider the case of moderate increasing returns described by the medium blue line. At this value of γ , g crosses f three times, first from below, then from above, and then again from below. At the first intersection point, we have $\rho_1^* < 1$ and $\omega_1^* > 1$; at the second one, we see that ρ_2^* approaches ρ_L as γ decreases toward γ_m ; at the third intersection point, we have $\rho_3^* > 1$ and $\omega_3^* < 1$. Equilibria are stable if and only if g crosses f from below are stable (see Appendix E), so the intermediate equilibrium is unstable. Thus, when γ increases across the threshold from weak to moderate increasing returns to scale, the equilibrium with decentralized production and low levels of commuting becomes unstable. In its place, two new equilibria arise with extreme values of ω . These extreme values of ω , in turn require that employment occur primarily in either the center or be divided between the two peripheral locations.

The light blue line in panel (b) describes g when γ is just above γ_m . As gamma approaches this threshold, for one of the two stable equilibria ω grows without bound (and occurs outside the frame of the figure) while ω approaches zero ever more closely in the other stable equilibrium. That is, just above the threshold, the stable equilibria approach corner patterns where all employment is either central or peripheral.

The dark blue line in panel (b) describes g when returns to scale are strong. As γ increases, the stable equilibrium with high ω converges toward the unstable equilibrium and when γ increases above the threshold between strong and moderate returns to scale, γ_s , it disappears. The only remaining equilibrium involves a moderate value of ω , that is, an equilibrium where employment is evenly distributed across the three locations. As γ increases, households get wealthier, consume more of the numéraire good, and become less sensitive to the cost of commuting. As this occurs, they bid away differences in land rent and distribute themselves more uniformly across the three locations. Thus we arrive at the surprising conclusion that a low degree of increasing returns leads to agglomeration while a high degree fosters dispersion.

Summing up, in a city with $\rho_0 < \rho_L$, as γ increases, the city converges to an interior pattern in which employment does not become highly concentrated in the center or the periphery. When returns to scale increases beyond the weak/moderate threshold, this equilibrium becomes unstable and two new equilibria arise. These equilibria involve extreme concentration of

employment in the center or in the periphery. As γ increases further, these two extreme equilibria become flatter, and ultimately, when γ crosses the moderate/strong threshold, we are left with a single equilibrium where employment is not highly concentrated in the center or periphery.

Panel (d) illustrates what occurs when returns to scale are moderate or strong in an economy where commuting costs are low and the productivity of land in production is relatively low ($\rho_0 > \rho_L$). The medium blue line illustrates the case when γ is moderate. Here we see that f crosses g only once and this crossing occurs when ω is close to zero. For such an economy, there is a unique equilibrium, and in this equilibrium most employment occurs in the peripheral locations. As γ decreases toward the threshold, a second equilibrium arises. This equilibrium involves a large value of ω , and hence, employment highly concentrated in the center. As γ increases so that returns to scale are strong, ω gradually increases, just as in panel (b) where $\rho_0 < \rho_L$.

Recalling that just below the γ_m threshold, this city had employment concentrated in the center, we can describe equilibrium throughout the range of γ . As returns to scale increases from low levels, employment is more and more concentrated in the center. When returns to scale cross the weak/moderate threshold this highly centralized equilibrium persists, but a second equilibria with employment concentrated in the periphery arises. As returns to scales increases away from the weak/moderate threshold, the equilibrium with employment concentrated in the periphery persists, but the one with centralized employment does not. As γ increases further, the distribution of employment becomes more uniform as wealthier households arbitrage away small differences in land price.

Propositions 8 and 9 confirm and refine this intuition about equilibrium with moderate and strong returns to scale, and its generality.

Before we turn to a more formal presentation of our results, we draw attention to the three features of the interior equilibria that we find most surprising. First, in some parts of the parameter space crossing the γ_m threshold involves the movement of nearly all employment from the center to the periphery, and in others from an interior equilibrium to one where nearly all employment is at the center or the periphery. Everywhere in the parameter space, equilibrium is always discontinuous at the γ_m threshold. Second, multiple interior equilibria may arise in the range of moderate γ , but in parts of the parameter space with low commuting costs or less productive land, the interior equilibrium is unique for any level of returns to scale. Finally, everywhere in the parameter space, for returns to scale strong enough, the city has a unique interior equilibrium outcome, and this outcome no longer involves highly concentrated employment in either the center or the periphery.

We now turn to a formal statement of our results.

6.1.1 Constant returns to scale

Under constant returns to scale equation (28) becomes $g(\rho; 0) = \rho^b$ so that (29) may be rewritten as,

$$\omega^{\frac{1+\varepsilon}{\varepsilon}} = \rho^b. \quad (33)$$

Proposition 5 *Under constant returns to scale, there exists a unique equilibrium. This*

equilibrium is interior and such that $0 < \rho^* < 1$ and $0 < \omega^* < 1$. Furthermore, if

$$\frac{\varepsilon}{1 + \varepsilon} < \frac{1 - \alpha}{\alpha\beta} \quad (34)$$

holds, then the equilibrium employment pattern is bell-shaped.

Proof: Proposition 4 implies that there is no corner equilibria when $\gamma = 0$. Since $g(\rho; 0)$ increases from 0 to 1 as ρ increases over $[0, 1]$, Lemma 1 implies that the two curves must cross exactly once. Furthermore, the intersection must occur strictly between ρ_0 and 1, which implies $0 < \rho^* < 1$. Since $g < 1$ over this interval, it must be that $\omega^* < 1$, while (33) implies $\omega^* > 0$. For the proof of (34), see Appendix G. Q.E.D.

The inequalities $0 < \rho^* < 1$ and $0 < \omega^* < 1$ imply that all rents and wages are positive and finite. Furthermore, the equilibrium land rent is higher in the center while the equilibrium wage is lower. Since condition (34) is equivalent to $b > 1$, and a bell-shaped employment pattern is equivalent to $\ell^* > 1$, so we have that $b > 1$ implies $\ell^* > 1$. It may seem surprising that (34) does not involve τ . We believe this reflects the fact that this condition is sufficient for $\ell^* > 1$, but not necessary.

We can refine our understanding of how the average preference for central work and residence affect equilibrium by examining the expressions for residential population and housing (23)-(26). Assume that wages and land rents are equal across locations so that $\omega = \rho = 1$. Substituting in the expressions for M_i and L_i we find that $M_0(1) = L_0(1) > M_1(1) = L_1(1)$. Therefore, central employment and residence is greater than in the periphery even though the different locations have the same relative pecuniary appeal. This reflects the average preference for central residence and workplace.

6.1.2 Weak increasing returns

The next two propositions describe the equilibrium when increasing returns to scale are weak.

Proposition 6 *Assume that $0 < \gamma < \gamma_m$. Then, there is a unique stable interior equilibrium and $\rho^* < 1$. Furthermore, if (34) holds, then the equilibrium employment pattern is bell-shaped and such that*

$$\frac{d\ell^*}{d\gamma} > 0 \quad \frac{d\rho^*}{d\gamma} < 0 < \frac{d\omega^*}{d\gamma}.$$

Proof: Under weak IRS, given Lemmas 1 and 2, f and g must intersect exactly once. This equilibrium is stable because f is increasing and g is increasing (see panels (a) and (c) of Figure 1). Furthermore, because $f(1) < 1 < g(1; \gamma)$, the intersection must occur at $\rho^* < 1$. This proves the first part of the proposition. See Appendix H for a proof of the second part. Q.E.D.

The substance of Proposition 6 seems intuitive. *As scale economies increase, the central business district attracts more workers*, while both the relative land price and relative wage increase as the land rent and wage at the center capitalize the agglomeration force resulting from increasing scale economies.

The comparative statics in Proposition 6 hold whenever $0 < \gamma < \gamma_m$. That is, whenever increasing returns to scale are weak. This is somewhat surprising because, consistent with our earlier discussion of panels (a) and (c) of Figure 1, there are two distinct types of equilibrium behavior with weak increasing returns to scale, depending on whether ρ_0 is larger or smaller than ρ_L . The following proposition formalizes our earlier discussion and describes how the two different types of equilibrium diverge as γ approaches γ_m .

Proposition 7 *Assume γ is slightly below γ_m .*

- i. *If $\rho_0 < \rho_L$, then the equilibrium wage ratio remains bounded and the limiting employment pattern remains interior as $\gamma \nearrow \gamma_m$.¹⁰*
- ii. *If $\rho_0 > \rho_L$, then $\omega^* \rightarrow \infty$ and the equilibrium employment pattern converges to $(0, 1, 0)$ as $\gamma \nearrow \gamma_m$.*

This proposition confirms that two distinct regimes are possible. When commuting costs are high, the full concentration of production in the central location requires prohibitively costly commuting. When commuting costs are low, almost full concentration of employment at the CBD occurs as long as the productivity of land in production is low enough to stop the migration of firms to the land abundant periphery. In this case, increasing returns become strong enough to complement the preference for central employment and generate almost full concentration of employment at the center.

6.1.3 Moderate increasing returns

When $\gamma > \gamma_m$, the function f remains unchanged, but the function g changes from an increasing to a decreasing function. When both f and g are decreasing, we are no longer assured of the existence of a unique equilibrium.

The following proposition formalizes the intuition suggested by figure 1 and confirms its generality.

Proposition 8 *Assume γ is slightly above γ_m .*

- i. *If $\rho_0 < \rho_L$, then there exist two stable interior equilibria, (ρ_1^*, ω_1^*) and (ρ_3^*, ω_3^*) , such that*

$$\omega_1^* > 1 > \omega_3^* \quad \text{and} \quad \rho_1^* < 1 < \rho_3^*,$$

as well as a third unstable interior equilibrium. Furthermore, as $\gamma \searrow \gamma_m$, the first two equilibrium employment patterns converge to, respectively, $(1/2, 0, 1/2)$ and $(0, 1, 0)$.

- ii. *If $\rho_0 > \rho_L$, then there exists a unique stable interior equilibrium (ρ^*, ω^*) such that:*

$$\omega^* < 1 \quad \text{and} \quad \rho^* > 1.$$

Furthermore, as $\gamma \searrow \gamma_m$, the equilibrium employment pattern converges to $(1/2, 0, 1/2)$.

¹⁰This pattern is bell-shaped when (34) holds.

Proof: See Appendix I.

This proposition is the counterpart of Proposition 7 when γ converges toward γ_m from above rather than from below. Proposition 8 establishes the existence of multiple stable equilibria when either commuting costs are high or the productivity of land in production is relatively low. When γ exceeds γ_m , the interior equilibrium, which was stable under weak IRS, becomes unstable while two new stable equilibria emerge. Formally, for any γ slightly larger than γ_m , there exists an arbitrary small $\Delta > 0$ such that the equilibrium employment patterns are given respectively by $((1 - \Delta)/2, \Delta, (1 - \Delta)/2)$ and $(\Delta/2, 1 - \Delta, \Delta/2)$. This result seems surprising. The assumption of heterogeneous agents is generally sufficient to smooth out discontinuities in equilibrium behavior (see, e.g., Anderson *et al.*, 1992).¹¹ What happens when γ belongs to (γ_m, γ_s) is discussed further below.

As γ rises above γ_s , we enter a third domain that is described below.

6.1.4 Strong increasing returns

The discussion of figure 1 shows that only a single interior equilibrium persists when γ exceeds γ_s . More specifically, we have:

Proposition 9 *If $\gamma > \frac{1+\varepsilon}{(1-\beta)\varepsilon} - \alpha \geq \gamma_s$, then there exists a unique interior equilibrium and this equilibrium is stable. Furthermore, the equilibrium employment pattern gets flatter as γ rises and converges to the uniform pattern when $\gamma \rightarrow \infty$.*

Proof: See Appendix J.

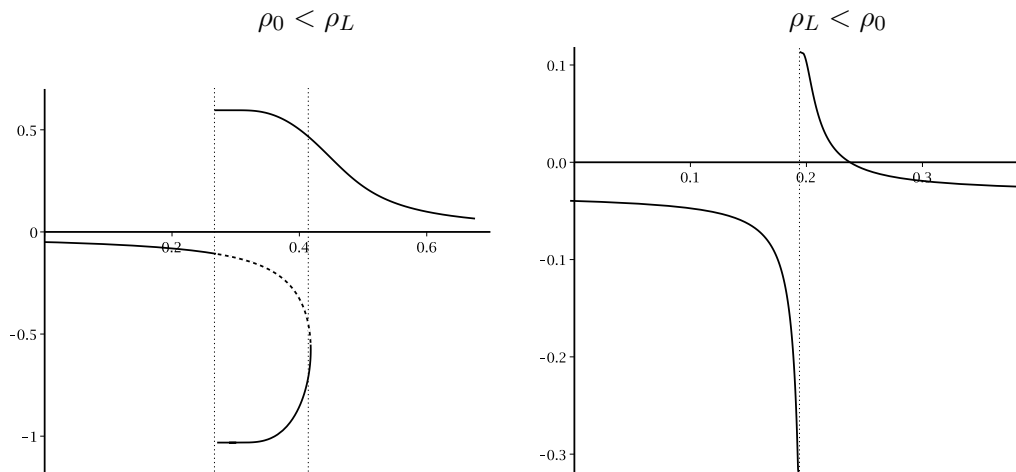

Remarkably, and contrary to general belief, increasing returns need not foster the concentration of activity. When increasing returns are strong, households are rich and, therefore, have a low marginal utility of income. In this case, production disperses as households avoid the cost of commuting, which rises with utility, by working at home.

To our knowledge, this result is new to the literature. While it has long been understood that increasing returns to scale could lead to multiple equilibria, the idea that sufficiently high increasing returns leads, once again, to a unique equilibrium is novel. Even more surprising, this equilibrium involves a growing dispersion of production as the degree of increasing returns rises. The intuition behind this result seems straightforward. As γ increases sufficiently, all else equal, wages must rise. This makes households better-off, which in turn raises the utility loss generated by commuting. As the marginal utility of income falls, households solve this trade-off by reducing the total amount of commuting, which leads to more dispersion.

Figure 2 summarizes propositions 5 to 9 for two examples satisfying $\rho_0 < \rho_L$ in panel (a) and

¹¹Propositions 6 and 7 show that there is a bifurcation at $\gamma = \gamma_m$, but do not actually describe the equilibrium at this point. Lemma 2 shows that ρ_L is the only admissible value of ρ such that g is defined at $\gamma = \gamma_m$. This suggests that we may consider (ρ_L, ω_L) as a candidate equilibrium, where $\omega_L = [f(\rho_L)]^{\frac{\varepsilon}{1+\varepsilon}}$. This requires that ρ_L belongs to the interval (ρ_0, ρ_1) . From the proof of Lemma 1 that $\rho_1 > 1$, and because $\rho_L < 1$, this requires $\rho_L < \rho_1$ always holds. However, the comparison of ρ_0 and ρ_L is less straightforward because ρ_0 is also smaller than 1 (see Lemma 1). If $\rho_L > \rho_0$, then (ρ_L, ω_L) is the only interior equilibrium. Otherwise, there is no interior equilibrium.

Figure 2: Equilibrium values of ρ as γ varies

Notes: In both panels the x -axis is γ and the y -axis is $\ln \rho$. The left panel illustrates all interior equilibria as γ varies when $\rho_0 < \rho_L$. The right panel shows the case where $\rho_L < \rho_0$.

$\rho_L < \rho_0$ in panel (b). In both panels, the x -axis describes γ and the y -axis describes $\ln \rho$. Both figure show all interior equilibria, but do not illustrate the corner equilibria required by 4.

When $\rho_0 < \rho_L$, there is a unique interior equilibrium in the range of constant and weak interior returns to scale. When γ increases across the γ_m threshold, the equilibrium bifurcates and we have two stable equilibria, one where central land rent is much higher than the peripheral and conversely. The weak increasing returns to scale equilibrium persists but becomes unstable. As γ increases further, the stable and unstable equilibrium involving high central land rent converge toward each other, and at the threshold between moderate and strong increasing returns, converge and disappear. For $\gamma > \gamma_s$, there is only a single equilibrium. As γ continues to increase, rents and employment in the two locations become more equal.

Behavior is simpler when $\rho_L < \rho_0$. There is a single equilibrium for γ in the range of weak increasing returns to scale, and the ratio of central to peripheral land rents increases without bound as γ increases toward γ_m . At the threshold between weak and moderate returns to scale, equilibrium shifts discontinuously to one where peripheral is higher than central land rent. As γ continues to increase, rents and employment in the two locations become more equal.

Figure 2 describes equilibrium for the entire range of γ for particular numerical examples. Our propositions are slightly less complete. Proposition 8 characterizes equilibrium just above the threshold separating weak and moderate increasing returns, γ_m , while proposition 9 characterizes equilibrium above γ_s , the threshold separating moderate and strong increasing returns. It is natural to expect that the behavior we observe near γ_m also occur throughout the full range of moderate increasing returns, (γ_m, γ_s) , as we observe in figure 2. In fact, we cannot rule out the possibility of more complicated equilibrium behavior for values of γ just below γ_s . However, we have been unable to find a counter example to contradict the conjecture that the results of proposition 8 hold throughout the range of moderate increasing returns.

Figure 3: Employment and residence ratios as commuting cost varies.

Notes: In panels, the x-axis is τ , the equilibrium value of $m = M_0/M_1$ is in red, and the equilibrium value of $\ell = L_0/L_1$ is in black. Other parameters used for these calculations are $\alpha = 0.9$, $\beta = 0.25$, $\varepsilon = 5$. In panel (a) $\gamma = 0.07$ and in panel (b) $\gamma = 0.7$.

6.2 Commuting cost and preference dispersion

We consider how interior equilibria vary as commuting cost or preference dispersion change, with a special emphasis on the cases of a homogeneous or infinitely heterogeneous population. We begin with figure 3. Both panels of this figure illustrate the equilibrium employment ratio $\ell = L_0/L_1$ and the equilibrium residence ratio $m = M_0/M_1$ as τ varies. The left panel illustrates an example where returns to scale are weak, $\gamma < \gamma_m$, and the right panel an example where they are strong, $\gamma > \gamma_s$. We omit the intermediate case to avoid the complication of multiple equilibria.

In the case of weak increasing returns, the concentration of employment in the center is increasing in commute costs for low levels of τ and decreasing for high levels of τ . Equilibrium employment is uniform as τ approaches either one or infinity. Residence is similar, but more elastic. Note that the peak of the employment and residence ratio loci occurs around $\tau = 1.2$. That is, where commuting results in a 20% utility penalty. For reference, Redding and Turner (2015) report an average round trip commute of about 50 minutes for an average American, this is about 12% of an eight hour work day. While it would be a mistake to take parameter magnitudes too seriously in such a stylized model, this calculation suggests that the complicated comparative statics illustrated in panel (a) may be empirically relevant.

The case of strong returns to scale illustrated in panel (b) is still more complicated. For low levels of τ the employment and residence ratio move in opposite directions as τ changes. For τ to the left of the peak of the employment ratio curve, the concentration of employment increases as commute costs increase and the behavior of residence is opposite. To the right of the peak, this behavior reverses until we reach the minimum of the two curves, when employment and residence begin to move together. Like the case of weak increasing returns illustrated in panel (a), as τ approaches one or infinity, the employment and residential patterns become flat. Note that the

scale of the x-axis in panel (b) is different from that in panel (a), and the peak of the employment ratio curve occurs around $\tau = 2$. The empirically relevant region of panel (b) likely lies to the left of the peak of the employment ratio curve, where decreases in τ decentralize employment and centralize residence.

Because τ and ε so often appear together in the analysis (as ϕ), it is natural to conjecture that the comparative statics for the two parameters are similar. As we show below, this conjecture is correct. With this said, it is more difficult to illustrate the comparative statics of ε because, as inspection of definition 2 shows, changes in ε can cause an economy to change between weak, moderate, and strong returns to scale, and therefore leads to more complicated behavior.

With these examples in place, we turn to a characterization of equilibria as τ approaches one and infinity, and as ε approaches zero or infinity.

Recalling that $\phi = \tau^{-\varepsilon}$, it is easy to show that $\phi \rightarrow 1$ when $\tau \rightarrow 1$ or when $\varepsilon \rightarrow 0$ and that $\phi \rightarrow 0$ when $\tau \rightarrow \infty$ or when $\varepsilon \rightarrow \infty$. Combining this observation with inspection of equation (21) and (22), we see that the average payoff from the choice of central versus peripheral workplace (or the corresponding payoffs from choice of residential locations) converge toward each other when ϕ goes to either zero or one. This is consistent with the convergence to a flat equilibrium for extreme values of τ that we see in figure 3, and suggests that such convergence may be general.

To show that this is the case, set $\phi = 0$ and $\phi = 1$ in (27) and (28), to obtain:

$$\begin{aligned} f(\rho)|_{\phi=0} &= \rho^{-1-\frac{1}{\beta\varepsilon}}, & f(\rho)|_{\phi=1} &= \frac{\rho - 2a\rho^{1+\frac{1}{\beta\varepsilon}} + 2(1+a)}{(1+a)\rho^{1+\frac{1}{\beta\varepsilon}} + 2\rho^{\frac{1}{\beta\varepsilon}} - a}, \\ g(\rho; \gamma)|_{\phi=0} &= \rho^{\left(\frac{1}{a} + \frac{\gamma}{\alpha\varepsilon}\right)} \rho^{\frac{\gamma\varepsilon/\alpha}{1-\gamma\varepsilon/\alpha} \frac{1+\varepsilon}{\varepsilon}}, & g(\rho; \gamma)|_{\phi=1} &= \rho^{\frac{b}{1-\gamma\varepsilon/\alpha}}. \end{aligned}$$

Evaluating each of these functions at $\rho = 1$ shows that $f(1)|_{\phi=0} = g(1; \gamma)|_{\phi=0} = 1$ and $f(1)|_{\phi=1} = g(1; \gamma)|_{\phi=1} = 1$. Hence, in both cases $\rho^* = 1$ is an equilibrium. As $\varepsilon \rightarrow 0$, hence $\gamma_m \rightarrow \infty$, this is the unique interior equilibrium because only weak increasing returns case is possible so that Proposition 7 applies.

When $\varepsilon \rightarrow \infty$ in $f(\rho)|_{\phi=0} = g(\rho; \gamma)|_{\phi=0}$, we have $\rho^{-1} = \rho^{\frac{1}{a}-1}$ whose unique solution is $\rho^* = 1$. It then follows from (27) that $\omega^* = 1$, which implies $\ell^*(1) = m^*(1) = h^*(1) = n^*(1) = 1$ when $\varepsilon \rightarrow \infty$. Using (23) and (24) we have $L_i^* = M_i^* = 1/3$ for $i = -1, 0, 1$ and it is easy to show that $s_{ij}^* = 0$ for $i \neq j$ and $s_{ii}^* = 1/3$. Thus, as the population becomes homogeneous, the equilibrium city consists of backyard capitalists who work where they live. In this equilibrium, land is shared between consumption and production according to the same proportion $H_i^*/N_i^* = a = \alpha\beta/(1-\alpha)$ across locations, so that residential land consumption increases with the land share in consumption and decreases with the land share in production.

The same patterns emerge as $\varepsilon \rightarrow 0$ and the population becomes infinitely heterogeneous. However, commuting patterns vary across the two types of equilibria. When $\varepsilon \rightarrow 0$, the payoffs for each of the nine location pairs become identical. As $\varepsilon \rightarrow \infty$, the payoff (22) attached to off-diagonal pairs goes to zero. In the former case, we have symmetric cross-commuting between any location pair, while we have no commuting at all in the latter case.

The following proposition summarizes this discussion.

Proposition 10 *Interior equilibrium employment, residential, housing, and commercial patterns converge to a flat pattern when one of the following condition holds:*

- i. $\tau \rightarrow 1$ or $\tau \rightarrow \infty$ and $\gamma < \gamma_m$ or $\gamma > \frac{1-\frac{1}{\beta}}{1-\beta} - \alpha$;
- ii. $\varepsilon \rightarrow 0$;
- iii. $\varepsilon \rightarrow \infty$ and $\gamma > \frac{1}{1-\beta} - \alpha$.

The intuition behind two of the four cases is transparent. As $\varepsilon \rightarrow 0$, preference dispersion increases. As this happens, taste heterogeneity over pairwise choices becomes increasingly important relative to commuting costs and, in the limit, households ignore land price and wage differences, and the distribution of households across pairs is uniform. Likewise, as $\tau \rightarrow \infty$ the cost of commuting grows so high that it never makes sense to commute. Since the distribution of types is the same across locations, households must be uniformly distributed across locations. In this case, only autarchy is possible and all households work where they live. In both cases, the distribution of residence and employment is uniform, although city functions differently in the two cases. When $\varepsilon \rightarrow 0$ we have ‘urban sprawl’, where many people commute and there is no city center. When $\tau \rightarrow \infty$ we have a city of backyard capitalists.

As $\varepsilon \rightarrow \infty$, preference dispersion disappears and households become homogenous. Simultaneously, the range of weak returns to scale collapses toward $\{0\}$. When returns to scale are constant, there is no longer a centralizing force in the model and the distribution of activity is uniform. The distribution of activity is also uniform when returns to scale are strong. This is less intuitive. When households no longer care about where they live and work, they focus on their own consumption only. In this case, *high increasing returns make them rich enough for households to avoid bearing the increasingly utility loss generated by commuting by residing and living at the same place*. In spite of strong increasing returns to scale, when the households are homogeneous the only interior equilibrium involves a uniform distribution of production activities across locations.

As $\tau \rightarrow 1$ something similar occurs. In the absence of increasing returns to scale, there is no reason for firms to concentrate, and so we arrive at a uniform distribution of activity because location does not matter anymore to agents. That this also occurs when increasing returns to scale are present is more puzzling. As shown by Panel (b) of Figure 2, m^* is larger than 1 because households earn a sufficiently high income to secure a large share of land in location 0 as a consequence of their average preference for the center (recall that ε is finite). As commuting costs fall sufficiently, the appeal of the center gets weak and the residential share at 0 decreases, while the employment share rises (see Figure 3). In the limit, the uniform pattern emerges.

In the absence of increasing returns to scale, there is no reason for firms to concentrate, and so we arrive at a uniform distribution of activity. That this also occurs when increasing returns to scale are present is more puzzling. As shown by Panel (b) of Figure 2, m^* is larger than 1 because households earn a sufficiently high income to secure a large share of land in location 0 as a consequence of their average preference for the center (recall that ε is finite). As commuting costs fall sufficiently, the appeal of the center gets weak and the residential share at 0 decreases, while the employment share rises (see Figure 3). In the limit, the uniform pattern emerges.

We regard these comparative statics as among the more surprising and important that we find for two reasons. First, in the monocentric city model, decreases in commuting costs lead households to spread out. Our results contradict this intuition. In our heterogeneous household model, *comparative statics on commuting costs are not monotone*. Second, as we describe in our review of the literature, discrete heterogeneous agent models, similar to ours, are the basis for a rapidly growing quantitative literature. Often, such quantitative exercises evaluate the effects of counterfactual changes in commuting costs. To the extent that these counterfactual exercises are comparative statics of commuting costs, our results suggest the qualitative features of such counterfactual exercises may change sign in response to changes in other incidental parameters.

7 A very short introduction to European urban history

Explaining the evolution of cities and their role in the process of economic growth over the course of history has long been central to urban economics, and the literature has long looked to history as a way to assess the relevance of our theories of cities. In what follows, we examine how an equilibrium city changes as the degree of increasing returns, γ , increases and compare these changes to the history of European cities from the pre-industrial period to the present.

We are agnostic about the reasons why γ increases, be it technological progress, human capital accumulation, or anything else. Reducing the long march of technological progress to the evolutions of a scalar necessarily abstracts from important details of the process. Yet, in spite of the parsimony of our model and assumptions, we see striking parallels between the way our model city changes with γ , and the changes we observe in European cities from pre-industrial period to the present.

We begin with a summary of the history of urban form and returns to scale since 1500, and then compare this history to the behavior of our model. To focus on returns to scale, this discussion omits any mention or analysis of other important trends, e.g., decreases in transportation cost and in the land intensity of production. We have three reasons for this. First, up until now, our understanding of the implications of changes in returns to scale has been restricted by the intractability of this problem: these results are our most novel. Second, as we will see, changes in returns to scale alone seem to have a remarkable ability to explain qualitative features of the history of cities. Finally, as important as other changes have been, increases in productivity are surely more important. By focusing on changes returns to scale we keep attention on the central economic force behind the industrial revolution.

The existence of various types of agglomeration effects in modern cities is well established, even if debate continues about exactly how large they are. We do not have systematic evidence about time series change in the importance of agglomeration effects, but three well-established facts from economic history suggests that returns to scale are increasing. First, during the period around 1500, de Vries (1984) reports 154 European cities with population above 10,000, while Bairoch (1988) reports 89 cities of at least 20,000. At this time, Europe (without Russia) had only between 10 and 12 cities of more than 100,000 inhabitants. By 1800, the count of cities with a population of at least 10,000 and 20,000 increased to 364 and 194, respectively. Similarly, the share of the urban population was low and rose slowly from 10.7 in 1500 to 12.2 percent in 1750. The urbanization rate was still around 12 percent in 1800, but grew rapidly to 19 percent in 1850, 38 percent in 1900, 51 percent in 1950, and 75 percent in 2000 (Bairoch, 1988). Before the

industrial revolution, Europe (without Russia) has no city of more than 2 million, but by 1910, four European cities cross this threshold (Berlin, London, Paris, and Vienna). Without a doubt, European cities have become progressively more attractive from the second half of the 19th century. While these increases are surely not entirely due to increases in returns to scale in production,¹² it is equally sure that stronger returns to scale are partly responsible.

Second, economic historians have documented many small changes in pre-industrial Europe that seem to have contributed to the productivity of cities. For example, Cantoni and Yuchtman (2014) observe the spread of Universities in 14th century Germany and argue that, by spreading knowledge of Roman law, these Universities contributed to larger and more productive market cities. Dittmar (2011) documents the spread of the printing press and finds that it contributed casually to the sizes of cities where it was introduced. Finally, de la Croix, Doepke and Mokyr (2018) argue that apprenticeship may have played a role similar to the one that Dittmar finds for the printing press by facilitating the transmission of tacit knowledge. In all, the history of the pre-industrial period points to slow increases in the productivity of cities through the growth of human capital and knowledge spillovers.

Finally, the nature of production has changed in a way that seems to argue for an increase in returns to scale. For the period prior to the industrial revolution, de Vries (1984) reports on the pervasiveness of proto-industrialization in manufacturing. Under this system, rural households performed manufacturing, often of textiles, using materials provided by manufacturers. It is hard to imagine a system of industrial production that more strongly suggests constant or decreasing returns to scale in manufacturing.¹³

Summing up, we can be confident that agglomeration and scale economies are positive in the modern economy and the available evidence strongly suggests that they were small or zero and increasing in the pre-industrial period. Taken together these two observations indicate a trend upwards.

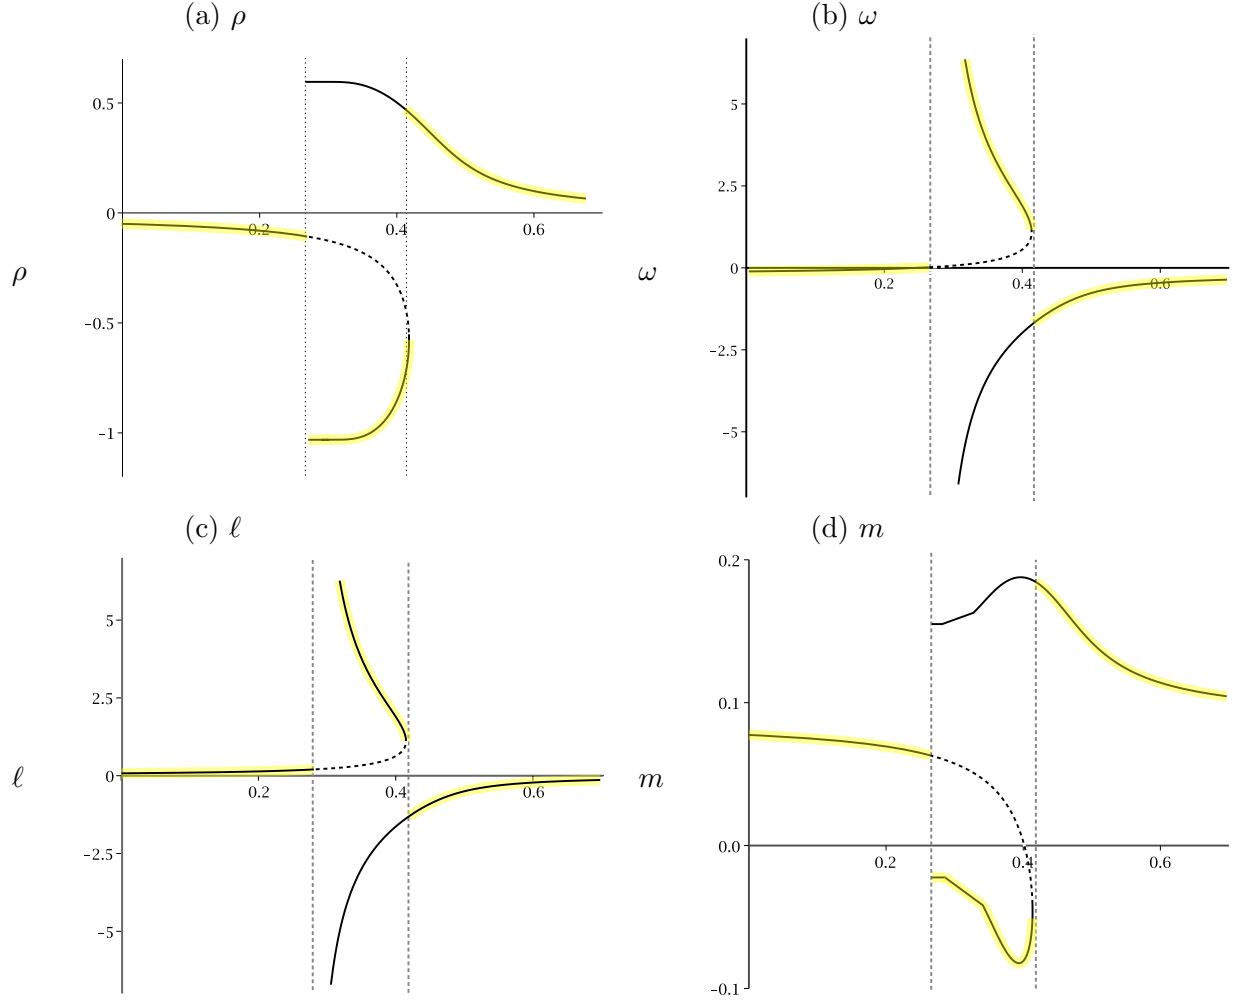

We now turn to a more ambitious undertaking, a stylized description of the evolution of urban form from the pre-industrial period to the present. de Vries (1984) describes cities in pre-industrial Europe as being organized as much for protection as production. Much of the population was employed in agriculture, either within city walls or without, manufacturing was at least as rural as urban, and the preponderance of urban residents were abjectly poor. While the absolute poverty of an average urban resident is clear, there is suggestive evidence from the US for the relative poverty of urban residents as well. Costa (1984) reports in a survey of US soldiers in the US civil war, early in the US industrial revolution, and finds that soldiers with urban backgrounds were shorter than those from rural backgrounds. According to Allen (2001), it was only after 1870 that real wages in Europe rose decisively above medieval levels.

Clark (1951) is the first effort to provide systematic evidence about patterns of city density. In this landmark study, Clark collects historical census data for a collection of US and European cities. While the precise time period he considers varies from city to city, for the most part his data begins early in the industrial revolution and continues until the early 20th century. His

¹²See Nunn and Qian (2011), for example.

¹³We note the Cesaretti *et al.* (2020) study finding that tax collection per capita increases with city size in England between 1450 and 1670. While this result seems relevant, it is unclear whether it reflects increases in the efficiency or effort of tax collectors, or increases in productivity of city residents, or simply the first nature advantages of larger pre-industrial cities.

Figure 4: Evolution of cities and returns to scale.

Notes: These figures illustrate how an equilibrium city evolves as γ increases. The solid dark lines indicate stable equilibrium outcomes, the dashed black lines indicate unstable equilibrium outcomes, and the highlighted portions indicate the particular equilibrium paths that we compare with history in the text. In all figures, the x-axis is γ and the y-axis is (a) $\ln(\rho)$, (b) $\ln(\omega)$, (c) $\ln(\ell)$, and (d) $\ln(m)$. In all four panels, the dashed vertical lines indicate the threshold values of γ , γ_m and γ_s . The parameter values on which these figures are based are $(\varepsilon, \tau, \alpha, \beta) = (3, 1.3, 0.8, 0.25)$.

findings are as dramatic as they are unequivocal. For the European and American cities in Clark's sample, center city density falls monotonically and the density gradient flattens over time.

Turning to the late 20th and early 21st centuries, Baum-Snow (2007) documents the decline in US central city population from 1950 to 1990, a phenomena earlier described by Meyer, Kain and Wohl (1965).¹⁴ Glaeser and Kahn (2004) document the changing spatial patterns of the late 20th century US. In particular, they find that employment follows decentralizing population and that peripheral urban residents of US cities tended to have much longer commutes than did central

¹⁴Angel-Garcia et al. (2015) document the corresponding phenomena in European cities.

residents. Related to this, Garreau (1992) documents the rise of ‘edge cities’ in late 20th century US, while McMillen and MacDonald (1998) provide econometric support for this idea using detailed data for Chicago. More recently, Couture and Handbury (2019) and Couture *et al.* (2020) document the a resurgence of central cities in the US.

Summing up, we arrive at the following stylized 500 year history of cities. During the pre-industrial period, population was dispersed and cities were small, poor and not obviously more productive than rural regions. In the early part of the industrial revolution, cities grew rapidly. Cities at this time had very dense centers and steep population density gradients. As the industrial revolution progressed, central city density decreased and the population density in peripheral suburbs increased. During the later part of the 20th century, we saw the rise of complicated poly-centric cities and longer commutes. In the 21st century, there is suggestive evidence for a slow resurgence of central cities.

Let us now compare this stylized history of cities to the behavior of our model. Figure 4 illustrates all possible interior equilibrium outcomes for our model as γ increases in a city satisfying $\rho_0 < \rho_L$. That is a city where either commuting costs are sufficiently high, the population is not too homogeneous, or land is sufficiently valuable in production (in the precise sense of Lemma 3). There are four panels in the figure. Panel (a) describes the evolution of ρ ; (b) describes ω ; (c) describes ℓ , the ratio of central to peripheral employment; and (d) describes m , the ratio of central to peripheral residence. In all four panels, we apply a logarithmic transformation to the y -axis to increase legibility. This compresses large values and assigns values between zero and one to negative values.

Our object in figure 4 is to demonstrate qualitative features of the way that equilibria change as γ increases. With that said, we rely on parameter values that are consistent with the available evidence. In every panel, the figures are based on a city where the fundamental parameters are $(\beta, \alpha, \tau, \varepsilon) = (0.25, 0.8, 1.3, 3)$, and γ ranges from zero to 0.7. A housing share of consumption, β , equal to 0.25 is conventional and in line with modern empirical evidence on the issue (Davis and Ortalo-Mangé, 2011). A labor share of 0.8 is large relative to the observed labor share in a modern economy, however, our model omits capital, so we are effectively consolidating the labor and capital share to drive down the land share of production to 0.2. This is a compromise value. It is likely too high for a modern economy and too low for the more agricultural preindustrial world. By choosing $\tau = 1.3$ we require that commuting from periphery to center results in about a 1/3 decline in welfare, all else equal. This is probably too large, but results in more legible figures than does a smaller value of τ . Similarly, $\varepsilon = 3$ is smaller than the values 5 or 6 suggested by Heblich, Redding and Sturm (2020),¹⁵ but contributes to the legibility of our figures. Setting $\varepsilon = 5$ does not change the figures qualitatively, but expands variation along the y -axis.

The range of γ described by the x -axes of the four panels of Figure 4 is 0 to 0.7. This range is large compared to modern estimates of agglomeration economies (around 0.05; see, e.g., Rosenthal and Strange, 2004). However, if we allow for any sort of compounding over the approximately 200 years since the industrial revolution began, considering values of γ up to 0.7 seems modest. The increase in returns to scale that we consider in Figure 4 is large only in

¹⁵We have seen that $\mu = \sigma - 1$ where μ is the heterogeneity parameter of the MNL and σ the elasticity of substitution of the CES. It is well known that the logarithm of a Gumbel-distributed variable is a Fréchet-distributed variable, so that $\mu = \varepsilon$. Therefore, we have $\varepsilon = \sigma - 1$. Since estimations of the elasticity of substitution of the CES suggest values of σ that vary from 6 to 8 (see, e.g., Bergstrand, Egger and Larch, 2013), it is reasonable to assume that ε varies from 5 to 7.

comparison to modern estimates of cross-sectional agglomeration effects. It is not large in comparison to any defensible measure of the increase in productivity between the 16th and 21st centuries. With this said, we repeat that our goal is to illustrate that the model can replicate qualitative features of history, not to approximate observed magnitudes.

In panel (a) we see that when γ is close to zero, ρ is less than one, and decreases gradually as γ increases. Recalling the definition of ρ , this means that for low levels of γ , central land rent is modestly higher than peripheral, and this ratio increases with γ . When γ reaches the threshold value separating weak from moderate returns to scale, γ_m , two new interior equilibria with extreme values of ρ emerge. In these equilibria, either central land rent is much higher than peripheral (the negative value of $\ln(\rho)$) or conversely, and the unique interior equilibrium that prevailed under weak increasing returns becomes unstable. As γ increases further, central and peripheral land rents converge in both equilibria. Ultimately, when returns to scale reach the strong increasing returns threshold, γ_s , the more centralized equilibria (i.e., $\ln(\rho) < 0$) converges with the in-between equilibrium and disappears. For cities following this more centralized equilibrium path, this leads to a second discontinuity in which ρ increases and central land rents decrease discontinuously to below peripheral land rents. As γ increases still further, central land rents gradually increase as the central city recovers from the second discontinuity.

In panel (b) we show the corresponding evolution of ω . As γ increases from 0 to γ_m , $\ln(\omega)$ increases from slightly below to slightly above 0, so that ω increases from slightly below (as required by Proposition 5) to slightly above one. Thus, at sufficiently low levels of returns to scale, the gap between central and peripheral workers is small, though peripheral workers are better off for γ near zero. As γ increases beyond γ_m , two extreme equilibria emerge. In one, central wages are much larger than peripheral wages. In this equilibria central land rent is also high, so that the positive equilibrium values of $\ln(\omega)$ correspond to the equilibria with negative values of $\ln(\rho)$. Conversely, along the second equilibrium path, peripheral wages are much higher than those in the center. As γ continues to increase, central and peripheral wages converge in both equilibria. When γ reaches the strong increasing returns to scale threshold, the more centralized equilibrium disappears and a city on this path experiences a discontinuous decrease in ω . After this drop, peripheral wages are higher than central wages. As γ increases still further, the central wages gradually recover.

Panel (c) shows the evolution of the logarithm of ℓ , the ratio of central to peripheral employment. Unsurprisingly, the equilibrium behavior of this ratio strongly resembles that of ω (a monotone transformation of the wage ratio). There is one noteworthy divergence. Both ω and ℓ are close to one and increase slowly as γ increases from zero. However, ℓ is always strictly greater than one in this range, so that there is always more employment in the center than the periphery, while ω can be below one for γ sufficiently close to zero.

Panel (d) shows the evolution of the logarithm of m , the ratio of central to peripheral residence. For low levels of γ , residence is concentrated in the center. As γ increases, this ratio gradually decreases as central employment gradually increases.

At the moderate returns to scale threshold, two new equilibria emerge in which residence is either highly concentrated in the center or in the periphery. The equilibrium with residence concentrated in the periphery is also the equilibrium where central land rent, wages and employment are very high relative to the periphery. That is, in one of the two equilibria, something very like a monocentric mill town emerges for values of γ just above γ_m . Employment

is highly concentrated in the center, central rents and wages are high, and most residents live in the periphery.¹⁶ As γ continues to increase, for both equilibria, residence becomes progressively more concentrated, as employment begins to disperse. Eventually, the path of residence begins to follow the path of employment. When γ reaches the strong returns to scale threshold, γ_s , cities with decentralized residence experience a discrete increase central residence. People move back into the city. As γ increases still further residence becomes less concentrated in the center as city's residence profile, like all other quantities in the figure, flattens out.¹⁷

We now consider the correspondence between the behavior of our model, and our stylized history of returns to scale and urban form. For the purpose of this exercise, let the pre-industrial period be a period of time during which returns to scale increase from zero to the threshold of moderate returns to scale, γ_m ; let the period from the industrial revolution until the mid-20th century be a period of time during which returns to scale increase from the moderate returns to scale threshold to the point in the moderate returns to scale domain where central residence reaches its minimum; and finally, let the post-industrial period beginning in the late-20th century correspond to a period of time when returns to scale increase beyond the point where central residential population reaches its minimum.

With this correspondence in place, we can compare our stylized history to the behavior of our model. We consider the more centralized of the two possible equilibria in the moderate increasing returns to scale range of γ . During the preindustrial period, cities were small and grew slowly. Employment and residence both concentrated in city centers, but the differences between center and periphery were modest. Employment in the center was at most only slightly more productive than in the periphery.

At the beginning of the industrial revolution, city centers grew rapidly. They became sites of highly concentrated employment, high wages and rents, even as residence was pushed out to the periphery, just as Clarke (1951) describes. No sooner did employment displace residence to the periphery, than employment began to follow people to be closer to their peripheral residences. Over time, the concentration of employment in central cities declines. With the arrival of the post-industrial period we see a continued decentralization of employment, although it still remains relatively concentrated in the center, and gradual increase in central residence, especially in the United States.

There does not seem to be a feature in our history that corresponds to the discontinuity that occurs at the boundary of moderate and strong increasing returns to scale, and so our ability to match history to our model ends, as does our stylized history, with a resurgence of central cities (Couture and Handsbury, 2020). It is natural to wonder whether some new innovation, perhaps related to information and communication technologies, will bring us up to this threshold. If so, the development of such technologies is likely to foster the growth of home-working, which would correspond to a (partial) re-dispersion of employment and residence as predicted by our model (Juhász *et al.*, 2020).

¹⁶We note the similarity of the rapid centralization of employment and migration of residence to the periphery to the changes that Heblich, Redding and Sturm (2020) observe in 18th century London. In their model, this effect arises as a consequence of changes in transportation costs, while we derive it as a consequence of increases in returns to scale.

¹⁷Note that the behavior of m has proved more resistant to analysis than have ρ , ω and ℓ , and in particular, none of our propositions address the behavior of m . Given this, we have less confidence in the generality of the behavior we see in panel (d) than for the other panels.

Summing up, while both our model and our description of history are stylized, the discussion above shows that many of the important features of the history of cities can be rationalized by our model and a trend upward in the strength of returns to scale.

8 Conclusion

Understanding how people arrange themselves when they are free to choose work and residence locations, when commuting is costly, and when increasing returns to scale affect production is one of the defining problems of urban economics. We address this problem by combining the discrete choice models employed by the recent quantitative spatial models literature, with the stylized geographies of classical urban economics. This permits a complete description of equilibria, throughout the parameter space.

Equilibrium behavior is surprising and interesting for a number of reasons. First, we find that corner equilibria where employment does not occur in one location exist in much of the parameter space. Given that the support of individual taste parameters is unbounded, this result is unexpected. Second, comparative statics as returns to scale increase contradict the conventional wisdom: increasing returns to scale in production can cause dispersion as well as agglomeration. Third, comparative statics on commuting costs also contradict conventional wisdom. As in the monocentric model, reductions in commuting costs can lead to dispersed economic activity, but they can also lead to greater concentration.

By combining classical urban economics and the QSM toolbox, we have also learned about how the two frameworks are different. Introducing heterogeneous agents with commuting costs is not merely a mathematical trick for solving a difficult choice problem, it is a fundamental change from classical urban economics. Introducing agents with heterogeneous preferences over work-residence location pairs results in an average preference for central work and residence. These average preferences are a *preference* for the central location in the assumed geography, and lead to centralized employment and residence even in the absence of increasing returns to scale. Neither preference is present in the older literature.

Two of our results should contribute to the refinement of quantitative spatial models of cities. First, for all parameter values, interior equilibria are discontinuous at the moderate increasing returns to scale threshold and, in our simple model, these discontinuities can be catastrophically large. This seems worrying for empirical application working within plausible measurement error of this threshold and suggests the importance of at least rudimentary numerical explorations of the part of the parameter space where multiple equilibria can occur. If a quantitative model is evaluated within reasonable measurement error of a catastrophic discontinuity, then the resulting uncertainty should probably be reflected in the conclusions drawn from such a model. Secondly, one of the most common applications of quantitative spatial models is to the evaluation of observed or counterfactual changes in commuting costs. Our results demonstrate that the qualitative effect of such changes is ambiguous and depends on both the level of commuting costs and on the values of other fundamental parameters. This suggests that robustness testing of the effects of changes in commuting costs are important as these comparative statics can change qualitatively as other parameters change. Our simple model does not provide a basis for thinking about how sensitive richer empirical models may be to this problem, but it does suggest that the possibility should at least be considered.

Finally, we show that the qualitative behavior of our model as returns to scale increase (along one of the possible equilibrium paths), can reproduce many of the qualitative features observed over the last 500 years of urban history in the Western world. Urbanization and increasing productivity are surely two of the most important economic phenomena in history and they appear to have been closely linked. That a simple economic geography model relating the two can reproduce basic features that we observe in the history of urbanization is striking, but it should probably not be surprising given that our model describes central issues in urban history.

Appendix

A. Proof of Proposition 2

We first evaluate κ for our three location city. Using (5), symmetry and (20) we have that

$$\kappa = \left[R_1^{\beta\epsilon} W_1^{-\epsilon} (2(1 + \phi^2) + 2\phi\omega + 2\phi\rho + \omega\rho) \right]^{-1}. \quad (\text{A.1})$$

Using the expression for utility maximizing choice shares (19, the definition of residential population (7), along with symmetry and (20), we have:

$$M_0 = s_{00} + 2s_{01} = \kappa R_1^{\beta\epsilon} W_1^{-\epsilon} (\rho(2\phi + \omega)).$$

Substituting for κ from (A.1), we have M_0 as a function of ρ and ω . Under symmetry, the residential pattern satisfies $2M_1 + M_0 = 1$. Substituting from (23) gives M_1 as a function of ρ and ω .

Using the expression for utility maximizing choice shares (19), the definition of employment (8), along with symmetry and (20), we obtain:

$$L_0 = s_{00} + 2s_{10} = \kappa R_1^{\beta\epsilon} W_1^{-\epsilon} (\omega(2\phi + \rho)). \quad (\text{A.2})$$

Substituting for κ from (A.1), we have L_0 as a function of ρ and ω . Under symmetry, the employment pattern satisfies $2L_1 + L_0 = 1$. Substituting from (A.2) gives L_1 .

To evaluate expressions for residential and commercial land, evaluate (10) for our three location model to get

$$\begin{aligned} R_0 H_0 &= \beta \kappa \left(W_0^{1+\epsilon} R_0^{-\beta\epsilon} + 2\phi W_1^{1+\epsilon} R_0^{-\beta\epsilon} \right), \\ R_1 H_1 &= \beta \kappa \left[\phi W_0^{1+\epsilon} R_1^{-\beta\epsilon} + (1 + \phi^2) W_1^{1+\epsilon} R_1^{-\beta\epsilon} \right]. \end{aligned}$$

Substituting from (A.1) and using (20) we have that

$$\begin{aligned} H_0 &= \beta \frac{W_0}{R_0} \frac{\rho\omega + 2\phi\rho\omega^{-\frac{1}{\epsilon}}}{\omega\rho + 2\phi\rho + 2\phi\omega + 2(1 + \phi^2)}, \\ H_1 &= \beta \frac{W_1}{R_1} \frac{\phi\omega^{\frac{1+\epsilon}{\epsilon}} + (1 + \phi^2)}{\omega\rho + 2\phi\rho + 2\phi\omega + 2(1 + \phi^2)}. \end{aligned}$$

Using the Cobb-Douglas property (15) and the land market clearing conditions (9), we get

$$1 - N_0 = a \frac{N_0}{L_0} \frac{\rho\omega + 2\phi\rho\omega^{-\frac{1}{\varepsilon}}}{\omega\rho + 2\phi\rho + 2\phi\omega + 2(1 + \phi^2)},$$

$$1 - N_1 = a \frac{N_1}{L_1} \frac{\phi\omega^{\frac{1+\varepsilon}{\varepsilon}} + (1 + \phi^2)}{\omega\rho + 2\phi\rho + 2\phi\omega + 2(1 + \phi^2)}.$$

Solving for N_0 and N_1 and using the expressions L_0 and L_1 from (24), we arrive at the commercial land use pattern,

$$N_0 = \frac{\rho + 2\phi}{(1 + a)\rho + 2\phi + 2a\phi\rho\omega^{-\frac{1+\varepsilon}{\varepsilon}}},$$

$$N_1 = \frac{\phi\rho + (1 + \phi^2)}{\phi\rho + a\phi\omega^{\frac{1+\varepsilon}{\varepsilon}} + (1 + a)(1 + \phi^2)}.$$

Substituting these expressions into the land market clearing conditions, $H_i + N_i = 1$, we find the housing pattern (25) and (26). Q.E.D.

B. Proof of Proposition 3

The land rent equilibrium condition (11) at $i = 0, 1$ leads to

$$R_0 = \left[\frac{\beta\kappa}{H_0} (W_0^{1+\varepsilon} + 2\phi W_1^{1+\varepsilon}) \right]^{\frac{1}{1+\beta\varepsilon}}, \quad (\text{B.1})$$

$$R_1 = \left[\frac{\beta\kappa}{H_1} (\phi W_0^{1+\varepsilon} + (1 + \phi^2) W_1^{1+\varepsilon}) \right]^{\frac{1}{1+\beta\varepsilon}}. \quad (\text{B.2})$$

Multiplying by R_j both sides of the land market balance condition (9), we get:

$$R_0 H_0 + R_0 N_0 = R_0 H_0 + \frac{1 - \alpha}{\alpha} W_0 L_0 = R_0, \quad (\text{B.3})$$

$$R_1 H_1 + R_1 N_1 = R_1 H_1 + \frac{1 - \alpha}{\alpha} W_1 L_1 = R_1. \quad (\text{B.4})$$

Dividing (B.3) over (B.4), we obtain:

$$r = \frac{R_0}{R_1} = \frac{R_0 H_0 + \frac{1-\alpha}{\alpha} W_0 L_0}{R_1 H_1 + \frac{1-\alpha}{\alpha} W_1 L_1}. \quad (\text{B.5})$$

It then follows from (B.1) – (B.2) that

$$R_0 H_0 = \beta\kappa \left(W_0^{1+\varepsilon} R_0^{-\beta\varepsilon} + 2\phi W_1^{1+\varepsilon} R_0^{-\beta\varepsilon} \right), \quad (\text{B.6})$$

$$R_1 H_1 = \beta\kappa \left[\phi W_0^{1+\varepsilon} R_1^{-\beta\varepsilon} + (1 + \phi^2) W_1^{1+\varepsilon} R_1^{-\beta\varepsilon} \right]. \quad (\text{B.7})$$

Using (19), the labor market balance conditions at $i = 0, 1$ are given by

$$L_0 = s_{00} + 2s_{10} = \kappa W_0^\varepsilon \left(R_0^{-\beta\varepsilon} + 2\phi R_1^{-\beta\varepsilon} \right),$$

$$L_1 = s_{11} + s_{01} + s_{-11} = \kappa W_1^\varepsilon \left[(1 + \phi^2) R_1^{-\beta\varepsilon} + \phi R_0^{-\beta\varepsilon} \right],$$

so that

$$W_0 L_0 = \kappa \left(W_0^{1+\varepsilon} R_0^{-\beta\varepsilon} + 2\phi W_0^{1+\varepsilon} R_1^{-\beta\varepsilon} \right), \quad (\text{B.8})$$

$$W_1 L_1 = \kappa \left[\phi W_1^{1+\varepsilon} R_0^{-\beta\varepsilon} + (1 + \phi^2) W_1^{1+\varepsilon} R_1^{-\beta\varepsilon} \right]. \quad (\text{B.9})$$

Plugging into (B.5) the expressions for $R_j H_j$ ($j = 0, 1$) given by (B.6)-(B.7) and the expressions for $W_j L_j$ ($j = 0, 1$) given by (B.8)-(B.9), we get after simplifications:

$$r = \frac{(1+a)w^{1+\varepsilon}r^{-\beta\varepsilon} + 2a\phi r^{-\beta\varepsilon} + 2\phi w^{1+\varepsilon}}{a\phi w^{1+\varepsilon} + \phi r^{-\beta\varepsilon} + (1+a)(1+\phi^2)}. \quad (\text{B.10})$$

Combining (12) with (13)-(14), we get:

$$w = \ell^\gamma \left(\frac{n}{\ell} \right)^{1-\alpha} \quad \text{and} \quad r = \ell^\gamma \left(\frac{n}{\ell} \right)^{-\alpha}. \quad (\text{B.11})$$

Dividing (B.8) by (B.9) yields:

$$\ell = w^\varepsilon \frac{r^{-\beta\varepsilon} + 2\phi}{\phi r^{-\beta\varepsilon} + (1 + \phi^2)}. \quad (\text{B.12})$$

Using (B.11) and (B.12), we get:

$$w^\alpha r^{1-\alpha} = \ell^\gamma = \left(w^\varepsilon \frac{r^{-\beta\varepsilon} + 2\phi}{\phi r^{-\beta\varepsilon} + (1 + \phi^2)} \right)^\gamma,$$

or, equivalently,

$$w = r^{-\frac{1-\alpha}{\alpha}} \left(w^\varepsilon \frac{r^{-\beta\varepsilon} + 2\phi}{\phi r^{-\beta\varepsilon} + (1 + \phi^2)} \right)^{\frac{\gamma}{\alpha}}. \quad (\text{B.13})$$

Since $\omega > 0$, the conditions (B.10) and (B.13) can be reformulated in terms of (ρ, ω) :

$$\rho = \left[\frac{(1+a)\rho\omega^{\frac{1+\varepsilon}{\varepsilon}} + 2a\phi\rho + 2\phi\omega^{\frac{1+\varepsilon}{\varepsilon}}}{\phi\rho + a\phi\omega^{\frac{1+\varepsilon}{\varepsilon}} + (1+\phi^2)(1+a)} \right]^{-\beta\varepsilon}, \quad (\text{B.14})$$

$$\omega = \rho^{\frac{1}{\alpha}} \left(\omega \frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} \right)^{\frac{\gamma\varepsilon}{\alpha}}. \quad (\text{B.15})$$

Solving (B.14) and (B.15) for $\omega^{\frac{1+\varepsilon}{\varepsilon}}$ yields (27) and (28). Q.E.D.

C. Proof of Lemma 1

As seen from (27), the denominator of $f(\rho)$ is an increasing function of ρ , which is unbounded from above and negative at $\rho = 0$. Therefore, the equation

$$D(\rho) \equiv (1 + a)\rho^{1+\frac{1}{\beta\varepsilon}} + 2\phi\rho^{\frac{1}{\beta\varepsilon}} - a\phi = 0$$

has a unique positive root ρ_0 . Clearly, $D(\rho) > 0$ if and only if $\rho > \rho_0$. Since $D(1) > 0$, it must be that $\rho_0 < 1$.

Next, it is readily verified using (27) that the numerator of $f(\rho)$ is a concave function which is positive at zero. It increases in the vicinity of 0 and then starts decreasing and goes to $-\infty$ as $\rho \rightarrow \infty$. Hence, the equation

$$N(\rho) \equiv \phi\rho - 2a\phi\rho^{1+\frac{1}{\beta\varepsilon}} + (1 + \phi^2)(1 + a) = 0$$

has a unique positive root ρ_1 . Clearly, $N(\rho) < 0$ if and only if $\rho > \rho_1$. Since $N(1) > 0$, it must be that $\rho_1 > 1$.

The numerator $N(\rho)$ and the denominator $D(\rho)$ of $f(\rho)$ have the same sign if and only if $\rho_0 < \rho < \rho_1$. This interval is not empty because $\rho_0 < 1 < \rho_1$. Since ρ_1 (resp., ρ_0) is the root of the numerator (resp., the denominator) of $f(\rho)$, it follows that $f(\rho)$ decreases from ∞ to 0 over (ρ_0, ρ_1) . Q.E.D.

D. Proof of Proposition 4

Only two patterns may be symmetric corner equilibria: $L_0^* = 0$ and $L_0^* = 1$.

Case 1: $L_0^* = 0$. In this case, the demand for commercial land at 0 is zero ($N_0^* = 0$). Hence, the land rent equilibrium condition (11) at $i = 0$ and $i = 1$ amount to

$$R_0 = \left[\frac{\beta\kappa}{H_0} 2\phi W_1^{1+\varepsilon} \right]^{\frac{1}{1+\beta\varepsilon}} > 0, \quad (\text{D.1})$$

$$R_1 = \left[\frac{\beta\kappa}{H_1} (1 + \phi^2) W_1^{1+\varepsilon} \right]^{\frac{1}{1+\beta\varepsilon}} > 0. \quad (\text{D.2})$$

Multiplying by R_j both sides of the land balance conditions (D.1) and (D.2), we get:

$$R_0 H_0 = R_0, \quad (\text{D.3})$$

$$R_1 H_1 + R_1 N_1 = R_1 H_1 + \frac{1 - \alpha}{\alpha} W_1 L_1 = R_1. \quad (\text{D.4})$$

Dividing (D.3) over (D.4), we obtain:

$$r = \frac{R_0}{R_1} = \frac{R_0}{R_1 H_1 + \frac{1 - \alpha}{\alpha} W_1 L_1}. \quad (\text{D.5})$$

It then follows from (D.1)-(D.2) that

$$R_0 = \beta\kappa 2\phi W_1^{1+\varepsilon} R_0^{-\beta\varepsilon}, \quad (\text{D.6})$$

$$R_1 H_1 = \beta\kappa(1 + \phi^2) W_1^{1+\varepsilon} R_1^{-\beta\varepsilon}. \quad (\text{D.7})$$

The labor market balance condition at $j = 1$ is given by

$$L_1 = s_{11} + s_{01} + s_{-11} = \kappa W_1^\varepsilon \left[(1 + \phi^2) R_1^{-\beta\varepsilon} + \phi R_0^{-\beta\varepsilon} \right],$$

so that

$$W_1 L_1 = \kappa \left[\phi W_1^{1+\varepsilon} R_0^{-\beta\varepsilon} + (1 + \phi^2) W_1^{1+\varepsilon} R_1^{-\beta\varepsilon} \right]. \quad (\text{D.8})$$

Plugging (D.6)-(D.7) and (D.8) into (D.5), we get after simplifications:

$$r = \frac{2a\phi r^{-\beta\varepsilon}}{\phi r^{-\beta\varepsilon} + (1 + a)(1 + \phi^2)},$$

or, equivalently,

$$\rho = \left[\frac{2a\phi\rho}{\phi\rho + (1 + a)(1 + \phi^2)} \right]^{-\beta\varepsilon}$$

whose unique solution is $\rho^* = \rho_1$. In other words, employment is evenly concentrated in the two peripheries and the central location is specialized in residential activities.

Case 2: $L_0^* = 1$. Following the same argument as in Case 1, we end up with the equation:

$$\rho = \left[\frac{(1 + a)\rho + 2\phi}{a\phi} \right]^{-\beta\varepsilon}$$

whose unique solution is given by $\rho^* = \rho_0$. That is, employment is fully concentrated at location 0. Q.E.D.

E. Proof of Lemma 3

It follows from the proof of Lemma 1 that ρ_0 is the unique solution of

$$D(\rho) \equiv (1 + a)\rho^{\frac{1+\beta\varepsilon}{\beta\varepsilon}} + 2\phi\rho^{\frac{1}{\beta\varepsilon}} - a\phi = 0. \quad (\text{E.1})$$

The expressions (30) and (E.1) imply that ρ_L and ρ_0 are functions of a . We next show that ρ_0 and ρ_L vary with a as follows,

$$\begin{aligned} \lim_{a \rightarrow 0} \rho_L &= 1, & \frac{d\rho_L}{da} &< 0, & \lim_{a \rightarrow \infty} \rho_L &= 1 - \phi, \\ \lim_{a \rightarrow 0} \rho_0 &= 0, & \frac{d\rho_0}{da} &> 0, & \lim_{a \rightarrow \infty} \rho_0 &= \phi^{\frac{\beta\varepsilon}{1+\beta\varepsilon}}. \end{aligned}$$

We can show that ρ_0 (resp., ρ_L) increases (resp., decreases) in a by applying the implicit function theorem to $D(\rho) = 0$ (resp., (30)). Observe further that, when $a \rightarrow \infty$ (resp., $a \rightarrow 0$), dividing

$D(\rho) = 0$ by a and taking the limit yields $\rho_0 = \phi^{\beta\varepsilon/(1+\beta\varepsilon)}$ (resp., $\rho_0 = 1$). Last, when $a \rightarrow \infty$ (resp., $a \rightarrow 0$), taking (E.1) at the power a and the limit yields $\rho_L = 1 - \phi$ (resp., $\rho_L = 1$).

To determine where ρ_0 and ρ_L intersect, we compare $\lim_{a \rightarrow \infty} \rho_L$ and $\lim_{a \rightarrow \infty} \rho_0$ by considering the equation

$$\phi^{\beta\varepsilon/(1+\beta\varepsilon)} + \phi = 1. \quad (\text{E.2})$$

Differentiating the LHS of (E.2) with respect to ϕ shows that it increases from 0 to 2 when ϕ increases from 0 to 1. The intermediate value theorem then implies that, for any given β and ε , the equation (E.2) has a unique solution $\bar{\phi}(\beta, \varepsilon) \in (0, 1)$, which increases with both β and ε .

The inequality $\rho_0 \leq \rho_L$ holds if $\phi^{\beta\varepsilon/(1+\beta\varepsilon)} \leq 1 - \phi$, which amounts to $\phi \leq \bar{\phi}$. If $\bar{\phi} < \phi \leq 1$, then there exists a unique value $\bar{a} > 0$ that solves the condition $\rho_L(a) = \rho_0(a)$. Consequently, if $a < \bar{a}$, then $\rho_0 \leq \rho_L$. If $a \geq \bar{a}$, then $\rho_0 > \rho_L$. Summing up, $\rho_0 \leq \rho_L$ if $\phi \leq \bar{\phi}$ or $a \leq \bar{a}$, and $\rho_0 > \rho_L$ when both conditions fail. Q.E.D.

F. Stability

We now show that a solution ρ^* of (29) is stable if and only if f crosses g from above at ρ^* .

Consider a differentiable function $h : \mathbb{R}_+ \rightarrow \mathbb{R}_+$. Say that $x^* \in \mathbb{R}_+$ is a fixed point of h if x^* solves the equation $h(x) - x = 0$. Say that x^* is stable if $h'(x^*) < 1$, and unstable otherwise.

Restate the equilibrium condition $f(\rho) = g(\rho; \gamma)$ as follows:

$$\rho = h(\rho; \gamma) \equiv f^{-1}(g(\rho; \gamma)), \quad (\text{F.1})$$

where $f^{-1} : \mathbb{R}_+ \rightarrow (\rho_0, \rho_1]$ is the inverse of f . It follows from Lemma 1 that f^{-1} is strictly decreasing, $f^{-1}(0) = \rho_1$, and $f^{-1}(\infty) = \rho_0$. We know from Lemma 2 that $g(\rho; \gamma)$ increases with ρ from 0 to ∞ for $\gamma < \gamma_m$, and decreases with ρ from ∞ to 0 for $\gamma > \gamma_m$. Hence,

$$h(0) = \begin{cases} \rho_1, & \gamma < \gamma_m, \\ \rho_0, & \gamma > \gamma_m, \end{cases} \quad \text{and} \quad h(\infty) = \begin{cases} \rho_0, & \gamma < \gamma_m, \\ \rho_1, & \gamma > \gamma_m, \end{cases}$$

and

$$h'(\cdot) \geq 0 \iff \gamma \geq \gamma_m.$$

As $\gamma \nearrow \gamma_m$ (resp., $\gamma \searrow \gamma_m$), $h(\cdot)$ converges to a piecewise constant function taking on one of two values, ρ_0 and ρ_1 , and displaying a downward jump (resp., an upward jump) at $\rho = \rho_L$.

For any solution ρ^* of (F.1), we have:

$$h'(\rho^*) = \frac{g'(\rho^*; \gamma)}{f'(\rho^*)}.$$

For $\gamma < \gamma_m$, we have $h'(\rho^*) < 0 < 1$, hence, ρ^* is stable. For $\gamma > \gamma_m$, we have: $h'_\gamma(\rho^*) < 1$ if and only if $|g'(\rho^*; \gamma)| < |f'(\rho^*)|$. In other words, ρ^* is stable if and only if f intersects g from above.

Note that there is an alternative formulation of (F.1).

$$\rho = \tilde{h}(\rho; \gamma) \equiv g^{-1}(f(\rho); \gamma). \quad (\text{F.2})$$

Applying the same logic to (F.2) as we applied to (F.1) leads to the opposite conclusion. That is, that a fixed point of \tilde{h} is stable if and only if f intersects g from *below*.

There is no a priori basis for preferring one of the two formulations to the other. Heuristically, the choice between them amounts to choosing the direction in which time moves. We resolve this indeterminacy in favor of (F.1) because this leads to a definition of stability where the unique equilibrium under constant returns to scale and the unique interior equilibrium under weak increasing returns to scale are both stable.

G. Proof of Proposition 5

Assume $\gamma = 0$. Since $0 < \rho^* < 1$, we may assume throughout that $\rho \in (0, 1)$. Note that the equilibrium employment pattern is bell-shaped if and only if $\ell^* > 1$, while (34) is equivalent to $b > 1$.

Some tedious calculations show that the equilibrium condition $f(\rho) = g(\rho; 0)$ may be rewritten as follows:

$$\frac{\left(\frac{a}{1+a}\rho^{-b} + \frac{1}{1+a}\rho^{-1}\right)^{-1} + 2\phi}{\phi\left(\frac{a}{1+a}\rho^b + \frac{1}{1+a}\rho\right) + 1 + \phi^2} \left(\frac{a}{1+a}\rho^{1+\frac{1}{\beta\varepsilon}} + \frac{1}{1+a}\rho^{b+\frac{1}{\beta\varepsilon}}\right) = 1. \quad (\text{G.1})$$

Since $1/x$ is convex, for every $\rho < 1$ Jensen's inequality implies

$$\left(\frac{a}{1+a}\rho^{-b} + \frac{1}{1+a}\rho^{-1}\right)^{-1} < \frac{a}{1+a}\rho^b + \frac{1}{1+a}\rho < \rho. \quad (\text{G.2})$$

Plugging (G.2) in (G.1) leads to

$$1 < \frac{\frac{a}{1+a}\rho^b + \frac{1}{1+a}\rho + 2\phi}{\phi\left(\frac{a}{1+a}\rho^b + \frac{1}{1+a}\rho\right) + 1 + \phi^2} \left(\frac{a}{1+a}\rho^{1+\frac{1}{\beta\varepsilon}} + \frac{1}{1+a}\rho^{b+\frac{1}{\beta\varepsilon}}\right).$$

Using $b > 1$ yields

$$\frac{a}{1+a}\rho^b + \frac{1}{1+a}\rho < \frac{a}{1+a}\rho + \frac{1}{1+a}\rho = \rho.$$

Since the function $\frac{x+2\phi}{\phi x+1+\phi^2}$ is increasing for all $x \geq 0$, we obtain

$$1 < \frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} \left(\frac{a}{1+a}\rho^{1+\frac{1}{\beta\varepsilon}} + \frac{1}{1+a}\rho^{b+\frac{1}{\beta\varepsilon}}\right). \quad (\text{G.3})$$

As (34) implies

$$\frac{1}{a} < 1 + \frac{1}{\beta\varepsilon} < b + \frac{1}{\beta\varepsilon},$$

while $\rho^* < 1$, we have

$$\frac{a}{1+a} (\rho^*)^{1+\frac{1}{\beta\varepsilon}} + \frac{1}{1+a} (\rho^*)^{b+\frac{1}{\beta\varepsilon}} < (\rho^*)^{\frac{1}{a}}.$$

Replacing the bracketed term in (G.3), we obtain the inequality:

$$1 < (\rho^*)^{\frac{1}{a}} \frac{\rho^* + 2\phi}{\phi\rho^* + 1 + \phi^2},$$

which is equivalent to $\rho^* > \rho_L$, hence $\ell^* > 1$ (see (32)). Q.E.D.

H. Proof of Proposition 6

Assume $0 < \gamma < \alpha/\varepsilon$. Since $\rho^* > \rho_L$, we have

$$f(\rho_L) > f(\rho^*) = g(\rho^*; \gamma) > g(\rho_L) \quad (\text{H.1})$$

because f is decreasing by Lemma 1 and g is increasing in ρ by Lemma 2. As shown by (31), $g(\rho_L)$ is independent of γ . Combining this with (H.1), we obtain $f(\rho_L) - g(\rho_L; \gamma) > 0$. Since $f(\rho^*) - g(\rho^*; \gamma) = 0$ while $f - g$ is decreasing by Lemmas 1 and 2, we have $\rho_L < \rho^*$ for all $\gamma < \alpha/\varepsilon$, which amounts to $\ell^* > 1$.

We now study the impact of γ on (i) ρ^* , (ii) ω^* and (iii) ℓ^* .

(i) Since $\partial g(\rho; \gamma)/\partial \gamma > 0$, applying the implicit function theorem to (29) leads to

$$\frac{d\rho^*}{d\gamma} = \frac{\partial g(\rho; \gamma)/\partial \gamma}{\partial f'(\rho)/\partial \rho - \partial g(\rho; \gamma)/\partial \rho} \Big|_{\rho=\rho^*} < 0,$$

where the numerator is positive because $\rho^* > \rho_L$ while the denominator is negative because $f(\rho)$ is decreasing and $g(\rho; \gamma)$ is increasing in ρ .

(ii) Differentiating (27) with respect to γ , we obtain:

$$\frac{1+\varepsilon}{\varepsilon} \omega^{\frac{1}{\varepsilon}} \frac{d\omega^*}{d\gamma} = \frac{df}{d\rho} \frac{d\rho^*}{d\gamma} > 0.$$

(iii) Observe that, combining (32) with (31), the equilibrium condition (29) can be restated as

$$\ell^{\frac{1+\varepsilon}{\varepsilon}} = \left(\frac{\rho + 2\phi}{\phi\rho + 1 + \phi^2} \right)^{\frac{1+\varepsilon}{\varepsilon}} f(\rho). \quad (\text{H.2})$$

Since $f(\rho)$ can be decomposed as

$$f(\rho) = \rho^{-\frac{1}{\beta\varepsilon}} \cdot \frac{\phi\rho + 1 + \phi^2}{\rho + 2\phi} \cdot \frac{1 + a \frac{1+\phi^2-2\phi\rho^{1+\frac{1}{\beta\varepsilon}}}{\phi\rho+1+\phi^2}}{1 + a \frac{\rho-\phi\rho^{-\frac{1}{\beta\varepsilon}}}{\rho+2\phi}}, \quad (\text{H.3})$$

plugging (H.3) in (H.2) leads to

$$\ell^{\frac{1+\varepsilon}{\varepsilon}} = \left(\frac{\rho^{-\frac{1-\beta}{\beta}} + 2\phi\rho^{-\frac{1}{\beta}}}{\phi\rho + 1 + \phi^2} \right)^{\frac{1}{\varepsilon}} \cdot \frac{1 + a^{\frac{1+\phi^2-2\phi\rho^{-\frac{1}{\beta}}}{\phi\rho+1+\phi^2}}}{1 + a^{\frac{\rho-\phi\rho^{-\frac{1}{\beta}}}{\rho+2\phi}}}.$$

The first term in the RHS clearly decreases in ρ . Since the numerator (resp., denominator) of the second term is decreasing (resp., increasing), the second term also decreases in ρ . Hence, the RHS is decreasing in γ . Combining this with $d\rho^*/d\gamma < 0$, we obtain $d\ell^*/d\gamma > 0$. Q.E.D.

I. Proof of Proposition 8

(i) Consider first the case when commuting costs are high. It then follows from (30) and Lemma 3 that $\rho_0 < \rho_L < 1 < \rho_1$. Therefore, for $\Delta > 0$ sufficiently small, we have:

$$\rho_0 + \Delta < \rho_L - \Delta < \rho_L + \Delta < 1 < \rho_1.$$

If γ is sufficiently close to α/ε (but still such that $\gamma > \alpha/\varepsilon$ holds), Lemma 2 implies the following inequalities:

$$\begin{aligned} g(\rho_0 + \Delta; \gamma) &< f(\rho_0 + \Delta), \\ g(\rho_L - \Delta; \gamma) &> f(\rho_L - \Delta), \\ g(\rho_L + \Delta; \gamma) &< f(\rho_L + \Delta), \\ g(\rho_1; \gamma) &> f(\rho_1) = 0, \end{aligned}$$

where the last inequality holds because (28) implies that, for $\gamma > \alpha/\varepsilon$, $g(\rho; \gamma) > 0$ for all $\rho > 0$ while $f(\rho_1) = 0$ for any γ by definition of ρ_1 . Therefore, by continuity of f and g , the equation (29) has at least *three* distinct solutions, which we denote as follows:

$$\rho_1^* > \rho_2^* > \rho_3^*.$$

Furthermore, the properties of function g imply the following:

$$\begin{aligned} \lim_{\gamma \searrow \alpha/\varepsilon} \rho_1^* &= \rho_1, \\ \lim_{\gamma \searrow \alpha/\varepsilon} \rho_2^* &= \rho_L, \\ \lim_{\gamma \searrow \alpha/\varepsilon} \rho_3^* &= \rho_0. \end{aligned}$$

The solution ρ_2^* matches the equilibrium of Proposition 7. As for the other two solutions, ρ^* and ρ_3^* , when γ is close enough to α/ε , we have $\rho^* > 1 > \rho_3^*$.

As $\gamma \searrow \alpha/\varepsilon$, it follows from Lemma 1 that $f(\rho^*)$ and $f(\rho_3^*)$ converge, respectively, to 0 and ∞ , which implies:

$$\lim_{\gamma \searrow \alpha/\varepsilon} \omega_1^* = 0 \quad \text{and} \quad \lim_{\gamma \searrow \alpha/\varepsilon} \omega_3^* = \infty.$$

Hence, $\omega_1^* < 1 < \omega_3^*$ when $\gamma\varepsilon$ is close enough to α . It then follows from (28) that

$$\lim_{\gamma\varepsilon \searrow \alpha} \ell_1^* = 0 \quad \text{and} \quad \lim_{\gamma\varepsilon \searrow \alpha} \ell_3^* = \infty.$$

(ii) Consider now the case of high commuting costs. Then, we know from the proof of Proposition 7 that there exists a value $\bar{a} \in (0, 1)$ such that

$$\rho_L \leq \rho_0 < 1 < \rho_1 \tag{H.1}$$

is satisfied for $a \geq \bar{a}$, and $\rho_0 < \rho_L < 1 < \rho_1$ holds otherwise. Under (H.1), there is a small $\Delta > 0$ such that the following inequalities hold:

$$\begin{aligned} g(\rho_1 - \Delta; \gamma) &< f(\rho_1 - \Delta), \\ g(\rho_1; \gamma) &> f(\rho_1) = 0. \end{aligned}$$

while $\rho^* > 1$ when γ slightly exceeds α/ε .

Furthermore,

$$\lim_{\gamma\varepsilon \searrow \alpha} (\omega_1^*)^{\frac{\varepsilon}{1+\varepsilon}} = f(\rho_1) = 0.$$

Since $\lim_{\gamma\varepsilon \searrow \alpha} \omega_1^* = 0$, $\omega_1^* < 1$ when $\gamma\varepsilon$ is sufficiently close to α . Last, using (32), we have:

$$\lim_{\gamma\varepsilon \searrow \alpha} \ell_1^* = 0.$$

Q.E.D.

8.1 J. Proof of Proposition 9

First, we show the existence and uniqueness of an equilibrium. Using (G.3) and (31), the equilibrium condition (29) becomes after simplifications:

$$\frac{1}{\phi\rho + 1 + \phi^2} \left(\frac{1 + a \frac{1+\phi^2-2\phi\rho^{1+\frac{1}{\beta\varepsilon}}}{\phi\rho+1+\phi^2}}{1 + a \frac{\rho-\phi\rho^{-\frac{1}{\beta\varepsilon}}}{\rho+2\phi}} \right)^\lambda = \rho^\mu \frac{\rho}{\rho + 2\phi}, \tag{J.1}$$

where λ and μ are defined by

$$\lambda \equiv \frac{\gamma\varepsilon - \alpha}{\gamma + \alpha} > 0 \quad \text{and} \quad \mu \equiv \frac{\gamma\varepsilon - \alpha - (1 - \alpha)(1 + \varepsilon)}{\beta\varepsilon(\gamma + \alpha)}.$$

The first term of the LHS of (J.1) decreases in ρ ; the second term also decreases because the numerator decreases while the denominator increases in ρ . Therefore, the LHS of (J.1) is a decreasing function of ρ . Furthermore, the RHS of (J.1) increases from 0 to ∞ in ρ when $\mu > 0$. It is readily verified that $\gamma > 0$ if and only if

$$\gamma > \frac{1 + \varepsilon}{(1 - \beta)\varepsilon} - \alpha.$$

Hence, (J.1) has a unique solution ρ^* . Panels (b) and (d) of Figure 1 show that this equilibrium is stable.

We now show that ℓ^* converges monotonically toward 1 when $\gamma > \gamma_s$ increases. Using (32), we obtain

$$\log \ell^* = -\frac{1}{\gamma\varepsilon/\alpha - 1} \log \left((\rho^*)^{\frac{1}{\alpha}} \frac{\rho^* + 2\phi}{\phi\rho^* + 1 + \phi^2} \right). \quad (\text{J.2})$$

Since $\rho^* > \rho_L$ under strong increasing returns, the expression under the log is greater than 1 and thus the RHS of (J.2) is negative. Furthermore, as ρ^* decreases with γ , the RHS of (J.2) increases with γ . In addition, the first of the RHS goes to 0 when γ goes to infinity. Consequently, ℓ^* increases and converges to 1. Q.E.D.
